CHAPTER 22

Phagocyte System and Disorders of Granulopoiesis and Granulocyte Function

Mary C. Dinauer, Peter E. Newburger, and **Niels Borregaard**

CHAPTER OUTLINE

DEFINITION AND CLASSIFICATION OF PHAGOCYTES
PHAGOCYTE DISTRIBUTION AND STRUCTURE
Regulation of Myelopoiesis
Granulocytes
Mononuclear Phagocytes
FUNCTION OF PHAGOCYTES
Humoral Mediators of the Inflammatory Response
Adhesion and Migration into Tissues
Recognition, Opsonization, and Phagocytosis
Cytocidal and Digestive Activity
Specialized Functions of Mononuclear Phagocytes
Specialized Functions of Eosinophils and Basophils
Pathologic Consequences of Phagocyte Activation and Inflammatory Response
QUANTITATIVE GRANULOCYTE AND MONONUCLEAR PHAGOCYTE DISORDERS
Neutropenia
Neutrophilia
Clinical States Associated with Alterations in Eosinophil Numbers
Basophilia and Basophilopenia
Monocytosis and Monocytopenia
DISORDERS OF GRANULOCYTE AND MONONUCLEAR PHAGOCYTE FUNCTION
Disorders of Adhesion
Disorders of Chemotaxis
Disorders of Opsonization and Ingestion
Disorders of Neutrophil Granules
Disorders of Oxidative Metabolism
Disorders of Cytokines and Impaired Phagocyte Function
Evaluation of Patients with Recurrent Infections

DEFINITION AND CLASSIFICATION OF PHAGOCYTES

Phagocytic leukocytes are bone marrow-derived cells that have the capacity to engulf and digest particulate matter. Phagocytes are essential for the host response to infection and injury and are equipped with specialized machinery enabling them to seek out, ingest, and kill microorganisms. Other functions include the synthesis and secretion of cytokines, pyrogens, and other inflammatory mediators, as well as the digestion of senescent cells and debris. These functions are important for resolution of injury and wound repair as well as linking innate to adaptive immunity.

The phagocyte system has two principal limbs: granulocytes (neutrophils, eosinophils, and basophils) and mononuclear phagocytes (monocytes and tissue macrophages). Both limbs participate in innate immunity and initiation of acquired immune responses. Neutrophils, the rapid effector cells of the innate immune system, circulate in the blood stream until encountering specific chemotactic signals that promote adhesion to the vascular endothelium, diapedesis into tissues, and migration to sites of microbial invasion or tissue injury. Mononuclear phagocytes also function as resident cells in certain tissues, such as lung, liver, spleen, and peritoneum, where they perform a surveillance role. This chapter is divided into three major sections. The first describes the normal distribution, structure, and function of granulocytes and mononuclear phagocytes. The second section reviews the clinical disorders associated with deficient or excessive phagocytic number. The third section focuses on disorders of phagocyte function, including both intrinsic phagocyte defects and conditions secondary to other disease processes.

PHAGOCYTE DISTRIBUTION AND STRUCTURE

Regulation of Myelopoiesis

Granulocytes and monocytes are produced in the bone marrow in a complex, highly regulated, and dynamic process that requires both specific hematopoietic growth

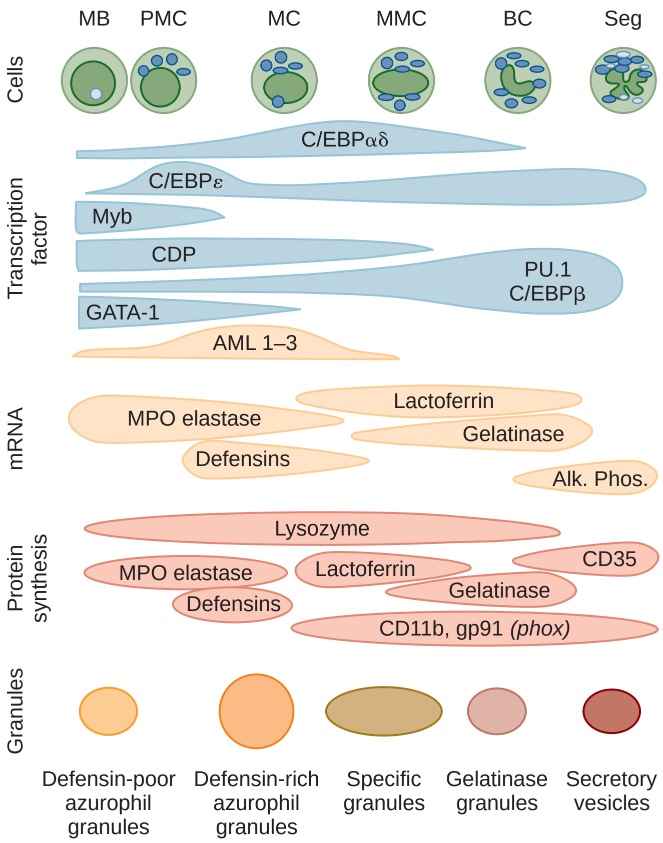

Figure 22-1 Neutrophil maturation. Neutrophil maturation and control of granule protein biosynthesis are achieved by the sequential and combined action of specific transcription factors, including PU.1, the C/EBP, and AML families, CDP, Myb, and GATA-1. The granules formed at any given stage of maturation will be composed of the granule proteins synthesized at that time. The different subsets of neutrophil granules are the result of differences in the biosynthetic windows during maturation and not the result of specific sorting between individual granule subsets. When the formation of granules ceases, it is believed that secretory vesicles will form. It cannot be ruled out that posttranscriptional control occurs, so biosynthesis of proteins may not always be a precise reflection of the corresponding mRNA levels. *AML,* Acute myelogenous leukemia; *BC,* band cell; *CDP,* CCAAT displacement protein; *C/EBP,* CCAAT/enhancer-binding protein; *MB,* myeloblast; *MC,* myelocyte; *MMC,* metamyelocyte; *MPO,* myeloperoxidase; *PMC,* promyelocyte; *Seg,* segmented cell (mature neutrophil). *(Modified from Borregaard N, Cowland JB: Granules of the human neutrophilic polymorphonuclear leukocyte.* Blood *89:3503–3521, 1997.)*

factors and an appropriate bone marrow microenvironment.[1] As reviewed in Chapter 6, multipotent, self-renewing hematopoietic stem cells (HSCs) give rise to lineage-restricted progenitor cells that divide and further differentiate in the bone marrow before their release into the intravascular compartment. Transcription factors of the PU.1 and CCAAT/enhancer binding protein (C/EBP) families play prominent roles in normal myelopoiesis (Fig. 22-1).[2] PU.1 is important for the development of early myeloid precursors and is absolutely essential for subsequent differentiation of the monocyte/macrophage lineage.[3,4] Early steps in the differentiation of granulocytes are dependent upon C/EBPα, whereas C/EBPε activity is required for terminal maturation beyond the metamyelocyte stage.[4] Cytokines that promote the proliferation and differentiation of neutrophils and monocytes from primitive precursor cells include interleukin (IL)-3, IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage CSF (M-CSF), and granulocyte CSF (G-CSF).[5-7] The latter two cytokines are relatively specific for the monocyte and neutrophil lineages, respectively. When apoptotic neutrophils are taken up by macrophages in tissues, they deliver a negative feed back via T-helper type (Th17) lymphocytes that results in reduction of G-CSF production.[8,9] During infections, activated macrophages release cytokines such as IL-1, IL-6, and tumor necrosis factor (TNF) that activate stromal cells and T lymphocytes to produce additional amounts of CSFs and increase the production of myeloid cells. This is termed *emergency granulopoiesis* and in mice has been shown to depend on G-CSF activation of *Stat3* and on C/EBPβ expression in granulocyte monocyte precursors (GMPs). However, in vivo feedback is impaired in *Tlr4–/–* and *Trif–/–*, but not *MyD88–/–* animals, thereby directly linking TLR-triggering to granulopoiesis.[10-13] IL-5[14,15] and IL-3 are the principal cytokines inducing human basophil growth and differentiation.[16] In addition to their regulatory role in hematopoiesis, hematopoietic growth factors can act on mature myeloid cells and stimulate their functional activities and survival.[17,18]

Myeloid differentiate also appears to be modulated by retinoic acid receptors and by transcriptional repressors such as Gfi-1.[19-22] The participation of retinoic acid in myeloid development was originally surmised from its ability to induce differentiation of myeloid leukemia cell lines and leukemic promyelocytes in patients with acute promyelocytic leukemia,[23] as discussed in Chapter 11.

Micro–ribonucleic acids (miRs) such as miR21, miR29a, miR125, miR130a, miR146, miR155, miR196b, and miR223 participate at several levels of myelopoiesis and in control of lineage decisions in the bone marrow.[24-27] MiRs are expressed at different stages during myelopoiesis, and several clusters can be identified depending on their expression profile during granulopoiesis.[28] Gfi-1 is a key repressor of miR21 and miR196b expression. Expression of these miRs promote monocytic differentiation and block granulocytic differentiation.[26] In addition to the well-known repression of translation, miRs can also regulate transcription by controlling the accessibility of promoters by epigenetic modifications as demonstrated on the nuclear factor IA promoter, which is silenced by miR223, allowing for terminal granulocytic differentiation.[28,29]

Granulocytes

Neutrophils

The neutrophil life span is traditionally divided into the bone marrow, circulating, and tissue phases. Approximately 14 days are spent in the bone marrow, where proliferation and the early stages of neutrophil differentiation are followed by the final stages of maturation and retention in a large, nonmitotic storage pool that is many times larger than the circulating and tissue neutrophil populations (Table 22-1).[30-33] Release is regulated by

TABLE 22-1 Neutrophil and Monocyte Kinetics

	Transit Time Range (hr)	**Total Cells ($\times 10^9$/kg)**
Neutrophils		
Marrow Mitotic Compartment		
Myeloblast	23	0.14
Promyelocyte	26-78	0.51
Myelocyte	17-126	1.95
Postmitotic Marrow Maturation and Storage Compartment

Vascular compartment	36-104	0.024
Tissue compartment	Days-months	Not known
Monocyte turnover rate	1×10^8/kg/day	

chemokines expressed on the cells, and their ligands are expressed by stroma cells. *CXCR4* and its ligand *CXCL12* retain cells,[34] and mutations in the CXCR4 receptor account for the warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome, an inherited neutropenia.[35,36] Whereas *CXCR2* and its ligands *CXCL1* and *CXCL2* promote neutrophil release. Also, the integrin $\alpha_4\beta_1$, known as very late antigen 4 (VLA-4) may tether bone marrow neutrophils to vascular cell adhesion molecule 1 (VCAM-1) expressed on bone marrow stromal cells.[37-40] Once released into the bloodstream, neutrophils have an estimated half-life of 6 to 10 hours and move between circulating and marginated pools in a reversible fashion. These estimates are based on several independent determinations using both in-vivo and in-vitro labeling techniques and transfusions, and they agree well with the estimates of neutrophils production rates of 10^9cells/kg/day and circulating neutrophil counts 2.5 to 4 × 10^9/L.[41] A recent controversial report suggests a half-life of 4 to 5 days both in humans and mice.[42] Neutrophils exit circulation by diapedesis between or through endothelial cells into tissue sites of infection or inflammation.[43-46] Once in the tissues, neutrophils are believed to live for another 1 to 2 days before undergoing apoptosis and engulfment by macrophages[47,48] or they form neutrophil extracellular traps (NETs) consisting of deoxyribonucleic acid (DNA) and antibiotic proteins from nucleus, granules, and cytosol in a regulated process called *netosis* that traps microorganisms.[49,50] This is discussed in more detail later in this chapter.

Myeloblasts are the earliest morphologically recognizable granulocyte precursors in the marrow and are identified by their relatively undifferentiated appearance with a large, oval nucleus, several prominent nucleoli, and few or no granules in a gray-blue cytoplasm in Wright-stained preparations. This stage of neutrophil differentiation is followed by the promyelocyte and myelocyte stages, which are distinguished by the appearance of distinct neutrophil granule populations (Table 22-2). Azurophilic, or primary, granules are formed during the promyelocyte stage and contain myeloperoxidase (MPO), bactericidal peptides, and lysosomal enzymes. The subsequent myelocyte stage is distinguished by the formation of peroxidase-negative specific, or secondary, granules containing lactoferrin. No further cell divisions occur after the myelocyte stage. The metamyelocyte, band, and mature neutrophil exhibit progressive nuclear condensation, accumulation of glycogen, and accumulation of tertiary, gelatinase-rich granules and secretory vesicles that are endocytic vesicles marked by albumin and Complement Receptor 1 (CR1) (CD35).[49] These neutrophil precursors can be identified and isolated by flow cytometry based on their surface antigen profile and forward and side scatter.[51]

In Wright-stained blood smears, the mature neutrophil is 10 to 15 mm in size with a multilobed, polymorphic nucleus that has highly condensed chromatin and a yellow-pink cytoplasm containing numerous granules as well as clumps of glycogen. The mean lobe count is usually slightly less than three. Circulating neutrophils appear round with some cytoplasmic projections and surface ruffling. The morphologic changes seen with neutrophil differentiation are accompanied by temporally coordinated changes in gene expression and protein synthesis (see Fig. 22-1). Transcription and translation of messenger RNAs (mRNAs) for MPO and cathepsin G, which are both primary granule constituents, are restricted to myeloblasts and promyelocytes.[52,53] In contrast, expression of the secondary granule proteins such as lactoferrin and transcobalamin I occurs in myelocytes and metamyelocytes.[53,54] Gelatinase expression occurs even later in maturation and is first detected in bands and bone marrow neutrophils.[55,56] The leukocyte β-integrin subunit CD11b is first detectable in myelocytes, and increases throughout the later stages of neutrophil differentiation. The $gp91^{phox}$ subunit of the respiratory burst oxidase complex is expressed relatively late in neutrophil maturation,[57] consistent with the observation that respiratory burst activity is not detected until the metamyelocyte stage.

The mature neutrophil, previously thought of as an "end-stage" cell, retains the capacity for inducible gene expression and protein synthesis even after release from the marrow cavity.[58-62] Diapedesis and exposure to cytokines induce neutrophil expression of mRNA transcripts for IL-1, IL-6, TNF-α, GM-CSF, M-CSF, and IL-8, which may promote recruitment and activation of both phagocyte and lymphocyte populations in the inflammatory response.[1,61]

Abnormalities in Neutrophil Morphology. Upon neutrophil activation by inflammatory signals, granule fusion can result in vacuolization and toxic granulation (prominent azurophilic granules). These morphological changes reflect a nonspecific response to inflammation and do not necessarily indicate the presence of bacterial infection. Large azurophilic granules but normal specific granules are seen in the Chédiak-Higashi[63] and the Alder-Reilly anomalies (both autosomal recessive [AR] traits), but neutrophil function does not appear to be affected in the latter. Döhle bodies can be seen in normal neutrophils at times of infection. These inclusions represent strands of rough endoplasmic reticulum that are retained from a more immature stage and stain bluish because of their high content of RNA and ribosomes. Döhle bodies in granulocytes and monocytes, in combination with leukopenia, giant platelets, and variable thrombocytopenia, characterize the May-Hegglin anomaly. This autosomal-dominant syndrome, like the similar Fechtner and Sebastian syndromes, is caused by mutations in the gene encoding non–muscle myosin heavy chain 9.[64]

Neutrophil hypersegmentation can be a sign of vitamin B$_{12}$ or folate deficiency. Hypersegmentation is also reported in small subset of neutrophils in the circulation that have reduced expression of L-selectin (CD62L).[65,66] These may represent a more mature subset approaching senescence and also are reported to be capable of suppressing T-cell activation during inflammation. Hypersegmented neutrophils with a mean of four lobes also occur as a rare autosomal dominant (AD) trait that is not associated with disease. Nuclear hyposegmentation is seen in Pelger-Huët anomaly, an AD trait caused by mutations in the gene encoding the lamin B receptor, an integral protein of the nuclear envelope.[67] Typically the nucleus is bilobed (often described as *pince-nez*) but has mature, coarse, and densely clumped chromatin. The nucleus remains round in the rare homozygote. Pelger-Huët anomaly must be distinguished from neutrophil band forms and from the acquired or "pseudo" Pelger-Huët form that can be seen with myeloproliferative disorders. Bilobed neutrophil nuclei are also seen in a rare functional disorder of neutrophil maturation, specific granule deficiency (SGD). In this disorder, the pink-staining specific granules are absent in peripheral blood neutrophils. Giant granules representing defective membrane targeting of proteins in secretory lysosomes are seen in Chédiak-Higashi syndrome (CHS) neutrophils, most prominently in the bone marrow. SGD and CHS are discussed in more detail later in this chapter.

Neutrophil Granule Biosynthesis and Classification. The numerous intracellular granules and vesicles in the neutrophil cytoplasm function as storage pools for cell surface receptors and as reservoirs of sequestered digestive and microbicidal proteins. Many compounds are multifunctional. For example, cathepsin G defensins and azurocidin are both antimicrobial and chemotactic for monocytes and T cells, which helps amplify the inflammatory response and link innate to adaptive immunity. The older classification of granules as either peroxidase-positive (azurophilic or primary) and peroxidase-negative (specific or secondary) has proven to be too simplistic.[51,60,61,68] Instead, neutrophil granules are a continuum from the earliest appearing azurophil granules formed in immature promyelocytes to gelatinase granules formed in band cells. The content of granules reflects the transcriptional profile during terminal neutrophil differentiation in the marrow.[1,69] A current classification of neutrophil granules is shown in Table 22-2, which summarizes the composition of their membranes and luminal (matrix) contents.

Azurophilic (primary) granules are defined histochemically by the presence of MPO, an enzyme in the oxygen-dependent killing pathway. This green heme enzyme lends it color to collections of mature neutrophils (pus) or myeloid leukemia cells in the bone marrow or extramedullary tumors ("chloromas"). Azurophilic granules also contain peptides and proteins that participate in oxygen-independent killing of microbes. Other components of the azurophilic granule matrix include neutral serine proteases and other digestive enzymes characteristic of lysosomes.

Specific (secondary) granules, which are uniquely found in neutrophils, are classically identified by their content of lactoferrin, an iron-binding protein that also has direct bactericidal activity. Specific granules also contain additional antibiotic substances, including lysozyme, lipocalin 2 (also known as neutrophil gelatinase–associated lipocalin; NGAL), a bacterial siderophore-binding protein, and the metalloproteases collagenase and gelatinase. The membrane of the secondary granules contains a major proportion of the neutrophil's supply of flavocytochrome *b558*, the electron carrier of the respiratory burst oxidase.[70,71] Specific granule membranes also contain a pool of receptors for adhesive proteins, TNF, and chemotactic formyl peptides.

Although specific granules contain collagenase and some gelatinase, most of the neutrophil's store of gelatinase is localized to the matrix of gelatinase (tertiary) granules, which also contain the membrane-associated metalloproteinase leukolysin (MMP-25). Tertiary granules are formed relatively late in neutrophil differentiation and are smaller and more easily mobilized for exocytosis than secondary granules. Secretory vesicles are formed in bands and mature neutrophils by endocytosis of the plasma membrane and serve as an important store of leukolysin as well as the adhesive protein Mac 1 (CD11b/CD18) and many other membrane receptors (see Table 22-2). Proteomics has permitted a more global view on neutrophil granule proteins.[72-74]

Neutrophil Cell Surface Receptors. A primary function of the mature neutrophil is to move rapidly into tissue sites to destroy invading microbes and clear inflammatory debris. To respond to inflammatory stimuli, the neutrophil is equipped with an array of cell surface receptors for adhesive ligands, chemoattractants, and cytokines that can be divided into groups based on their structure and the major intracellular signaling pathway to which they are linked (Table 22-3).[75] Many of these surface proteins are pattern-recognition molecules such as Toll-like receptors (TLRs) and formyl peptide receptors,[76-80] reflecting the neutrophil's role in the innate immune response. Microdomains in the plasma membrane also known as lipid rafts, which are enriched in cholesterol, glycosphingolipids and glycosylphosphatidylinositol (GPI)-anchored proteins, and CD11b/CD18, can function as pattern recognition structures by virtue of their glycosphingolipids such as lactosylceramide (CDw17), the lipopolysaccharide (LPS)-binding GPI-anchored protein CD14 and the carbohydrate-binding domain of CD11b. These aggregates can then signal intracellularly via the associated integrins but likely also via lipid tail interactions of CDw17 and the tyrosine kinase Lyn attached to the inside of the membrane via its lipid-tail.[81]

The signal transduction cascades triggered upon ligand binding to neutrophil receptors are complex and probably redundant.[82-88] TLRs recognize structures specific for microorganisms, the pathogen-associated molecular patterns (PAMPs) such as LPS, lipoteichoic acid, and flagellin,[89] but they also host molecules associated with cellular stress and injury, the damage-associated molecular patterns (DAMPs) such as heat-shock protein 60 and DNA.[76] A common early event downstream of neutrophil receptor binding is activation of phospholipase C (PLC), which hydrolyzes the membrane phospholipid, phosphatidylinositol 4,5-bisphosphate (PIP_2) to generate two important second messengers, diacylglycerol and inositol 1,4,5-triphosphate (IP_3), which in turn cause release of calcium from intracellular stores and activate protein kinase C. Changes in intracellular calcium concentration are important for neutrophil degranulation and secretion and for phagolysosome fusion during phagocytosis.[85] Activation of phosphoinositide 3′-kinase (PI3K) is another common early event that catalyzes the phosphorylation of PIP_2 to generate a third important lipid messenger, phosphatidylinositol 3,4,5-trisphosphate (PIP_3).[90] Neutrophil activation is also accompanied by alterations in the phosphorylation status of intracellular proteins, as

TABLE 22-3 Receptors in Neutrophils

Receptor Grouping	Examples	Structural Characteristics
G-protein linked	fMLP, C5a, PAF, LTB_4, IL-8, chemokines	Seven-transmembrane–spanning domains (serpentine); linked to heterotrimeric GTP-binding proteins
Membrane tyrosine kinases	PDGF	Integral membrane protein, intrinsic tyrosine kinase activity; ligation leads to receptor dimerization and cross (“auto”) phosphorylation
Tyrosine kinase linked	FcγRIIa, GM-CSF	FcγRII is a member of the immunoglobulin family of receptors The GM-CSF receptor is an 84-kD transmembrane protein related to receptors for IL-2 and IL-6 Ligation of receptor activates cytosolic tyrosine kinases
GPI linked	FcγRIIIb, DAF, CD14	Receptors with no transmembrane or intracellular domains. May associate with a partner receptor to mediate signal transduction
Adhesion molecules	β_2 Integrins L-selectin	β Integrins are heterodimers with relatively long cytoplasmic tails L-selectin has an extracellular lectin-binding domain and a very short cytoplasmic tail Ligation results in potentiation of the oxidative burst and phagocytosis in adherent cells, calcium signaling, actin cytoskeletal changes, and upregulation of gene expression
Ceramide linked	TNF	Single-membrane-spanning glycoproteins; ligation activates membrane-bound sphingomyelinase with generation of ceramide, which in turn activates a 96-kD protein kinase

DAF, Decay-accelerating factor; *FcγR,* Immunoglobulin G Fc receptor; *fMLP,* N-formyl-methionyl-leucyl-phenylalanine (formyl peptide); *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *GPI,* glycosylphosphatidylinositol; *GTP,* guanosine triphosphate; *IL,* interleukin; *LTB_4,* leukotriene B_4; *PAF,* platelet-activating factor; *PDGF,* platelet-derived growth factor.

regulated by protein kinase C, tyrosine kinases and phosphatases, and serine/threonine kinases of the mitogen-activated protein (MAP) kinase family.[88,91,92] Guanine nucleotide binding proteins play important roles in neutrophil signal transduction. These include the heterotrimeric guanosine triphosphate (GTP)-binding proteins that are coupled to the seven transmembrane-spanning domain (serpentine or heptahelical) receptors for chemokines and other chemoattractants[93-95] and the low molecular weight guanosine triphosphatases (GTPases) of the Ras superfamily.[82] The latter category includes p21Ras itself, which can be activated via chemoattractant receptors,[96] and the Rho family GTPases Rho, Rac, and Cdc42, which are involved in the regulation of many neutrophil responses, including adhesion, the respiratory burst–reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, and actin remodeling during migration and phagocytosis.[82] A dominant-negative form of the Rac2 GTPase has been identified in an infant with recurrent deep-seated bacterial infections and leads to multiple defects in phagocyte function.[97-99]

Signaling through these receptors is subject to positive and negative modulation. Triggering receptors expressed on myeloid cells (TREMs), of which TREM-1 is expressed on neutrophils, potentiate the signaling through TLRs. TREMs signal through an intracellular adaptor protein, DNAx activating protein (DAP) of 12 kD, DAP12.[100-103] DAPs contain an immunoreceptor tyrosine–based activation motif (ITAM), which when phosphorylated, actives the protein tyrosine kinase Syk, which activates PI3K and phospholipase Cγ (PLCγ) via Bruton tyrosine kinase and thus potentiates the signals generated through TLRs, chemokine receptors, and integrins.[103]

Neutrophils express high levels of G-CSF and GM-CSF receptors. These receptors signal through Janus kinases (JAKs),[104] which dock to phosphorylated tyrosine residues in the cytoplasmic tail of the receptors, and from there phosphorylate and activate STAT-3 and -5 that induce transcription of several genes, in particular cytokines. The signaling through receptors activated via tyrosine phosphorylation is modulated by two different mechanisms, suppressors of cytokine signaling (SOCS) and immunoreceptor tyrosine–based inhibitory motifs (ITIMs). SOCS-3 is induced by activated STAT-3 and binds to and blocks phosphotyrosines in the activated growth factor receptor.[105,106] In contrast, activation of receptors such as signal inhibitory receptor on leukocytes-1 and CD300a that contain an ITIM recruits phosphotyrosine phosphatases to dephosphorylate the activated cytokine receptors and reduce signaling.[107-110]

Neutrophil Subsets. Circulating neutrophils are traditionally viewed as one homogenous population. However, it is known that two subsets can be identified based on the presence or absence of CD177. The fraction of neutrophils that express this antigen varies from 0 to 100 amongst individuals but is stable through life.[111] CD177 is the surface receptor for proteinase 3, the antigen associated with Wegener granulomatosis, and signals generated via CD177 are believed to play a major role in this disease.[112] As mentioned, a subpopulation of hypersegmented neutrophils that also have reduced L-selectin expression has been reported, which may indicate a more mature neutrophil population with T-cell suppressive activity.[65,66] Recently, a specific granule protein with antibacterial properties, OLFM4 was found to be expressed in 25% of human granulocytes with wide but constant variation among individuals.[113]

Eosinophils

Like the neutrophil, the eosinophil is compartmentalized in the bone marrow into mitotic and storage pools; these usually constitute no more than 0.3% of the nucleated bone marrow cells. Eosinophils arise from a progenitor cell, the CFC-Eo, that is committed at a relatively early stage to differentiate into eosinophils instead of neutrophils and monocytes in the bone marrow. GATA-1, PU.1, and C/EBPs play critical roles in the transcriptional regulation of eosinophil lineage commitment and differentiation.[114-116] Morphologic differentiation and maturation of the eosinophil parallel that of the neutrophil series, and its characteristic eosin-staining–specific granules are prominent by the myelocyte stage. IL-3, IL-5, and GM-CSF mediate eosinophil production in the marrow; IL-5, IL-13, chemokines (such as eotaxins [CCL11] regulated on activation, normal T cell expressed and secreted [RANTES; i.e., CCL5]), and leukotrienes [LTB4] play key roles in regulating eosinophil differentiation, chemotaxis, and functional activation.[14,15,117-119]

After leaving the circulation, the majority of mature eosinophils reside in tissues, with a blood-to-tissue ratio estimated to be 1:300 to 1:500. The life span of tissue eosinophils is not known but may be several weeks, whereas the half-life in blood is around 24 hours.[120] Eosinophils typically localize in areas exposed to the external environment, such as the tracheobronchial tree, gastrointestinal (GI) tract, mammary glands, and vagina and cervix. As discussed later, eosinophils have both immunoenhancing and immunosuppressive functions and play a role in helminthic infection, allergy, and the responses to certain tumors.[114-116,119,121-123]

The mature eosinophil is slightly larger than the neutrophil, with a diameter of 12 to 17 μm. The nucleus is characteristically bilobed, although multiple lobes can be seen in patients with eosinophilia of diverse causes. The cytoplasm has prominent and morphologically distinctive granules that stain strongly with acid aniline dyes because of their high content of basic proteins.

Like the neutrophil, the mature eosinophil is endowed with the capacity for chemotaxis, phagocytosis, degranulation, and the synthesis of reactive oxidants and arachidonate metabolites.[14,124,125] Eosinophils may also undergo a process similar to neutrophil netosis.[126-128] Eosinophil cell surface membranes express a wide variety of molecules, including receptors for immunoglobulins and members of the immunoglobulin superfamily; cytokine receptors; adhesion molecules; chemokine, complement, and other chemotactic receptors; and major histocompatibility complex (MHC) class I and II and costimulatory molecules.[14,124]

The distinctive mature eosinophil granules are membrane-bound organelles, 0.15 to 1.5 μm in length and 0.3 to 1 μm in width that contain a variety of enzymes and cytotoxic proteins.[14,124] These eosin-staining specific granules are large ovoid bodies that contain an electron-dense crystalloid core surrounded by a less dense matrix. The eosinophil major basic protein (MPB) makes up about 50% of the dense crystalloid core of the eosinophilic specific granule.[129] MBP from eosinophils induces histamine release from basophils and mast cells[130] and also an autocrine degranulation of eosinophils.[116] Release of proteins from these large granules is different from the degranulation process of neutrophils, where intact granules fuse with the surface membrane and empty their entire content and the membrane of granules is incorporated into the surface membrane. Instead, because the eosinophil is active in tissues, its granules swell and a tubulovesicular system extends from the granules to the surface permitting piece meal degranulation (PMD), or the graded release of granule content.[129,131,132] Eosinophil peroxidase plays an important role in the antihelmintic function of eosinophils[133,134] and utilizes bromate to generate hypobromous acid from hydrogen peroxide.[135,136]

Much less common than eosinophil-specific granules are the primary granules characterized by their content of a lysophospholipase, the Charcot-Leyden crystal (CLC) protein that can polymerize to form the bipyramidal hexagons that are CLCs.[14,124] CLCs are typically found in areas of eosinophil degeneration, such as sputum from asthmatic patients, nasal mucous of patients with allergies, stools of patients with parasitic infections, and the pleural fluid of patients with pulmonary eosinophilic infiltrates. The CLC lysophospholipase[137] catalyzes the hydrolysis and inactivation of lysophospholipids generated by phospholipase A_2, thus preventing the generation of proinflammatory arachidonic acid metabolites. The CLC protein composes about 5% of the total protein in eosinophils.

Slightly more numerous but distinctly smaller than primary granules are the small type granules whose content is not well characterized and secretory vesicles, which like secretory vesicles of neutrophils contain the NADPH oxidase flavocytochrome *b558*, and albumin, indicating an origin as endocytic vesicles; however, in eosinophils these may also be part of the tubulovesicular system of PMD.[138]

Eosinophil granule products, particularly MBP, eosinophil peroxidase, and eosinophil neurotoxin, are toxic to tissues, including the heart, lungs, and brain.[14,124] These mediate many of the adverse clinical complications of eosinophilia and hypereosinophilic syndrome (HES), such as Löffler endocarditis and pneumonia.[139,140]

Basophils and Mast Cells

Basophils and mast cells are believed to share a common progenitor cell,[141-146] but mast cells leave the bone marrow to proliferate and mature in tissues, whereas full differentiation of basophils occurs in the bone marrow over 7 days before their release into the bloodstream; they are not normally found in the connective tissues.[147] Basophils account for approximately 0.5% of the total circulating leukocytes and 0.3% of nucleated marrow cells.[148] Mature basophils have a bilobed nucleus. Although basophils are distinctly smaller (5 to 8 μm) than mast cells (20 μm), they both contain large metachromatic granules that stain purple or bluish with Wright stain because of their high content of sulfated glycosaminoglycans. These granules are rich in heparin-type and chondroitin sulfate-type glucosaminoglycans linked to the serglycin protein backbone that is responsible for packing the cationic proteins, histamine, and kallikrein.[149-154] Mast cells and basophils express high affinity receptor for the Fc portion of immunoglobulin E (IgE), which is an important trigger for release of granule contents and production of arachidonic acid metabolites in anaphylactic degranulation on their plasma membrane,[155] and are key effector cells in certain hypersensitivity reactions.[141,149,150,156] However, mast cells lack receptors for IL-2, IL-3, and CD11b/CD18 that are present on basophils.[16] The heparin of basophils appears to have poor anticoagulant activity. Basophil granules also contain small amounts of MBP as well as serine proteases. Basophils synthesize and secrete IL-4 and IL-13 and may thus mediate a link between the innate and adaptive immune systems for generation of Th2 lymphocyte responses.[150,157] Murine mast cells can secrete a wide variety of mitogenic or inflammatory cytokines (including IL-1, IL-3, IL-4, IL-5, and IL-6), chemokines, GM-CSF, and TNF-α, that are likely to play an important role in leukocyte recruitment and inflammation.[158,159]

Mast cells are ordinarily distributed throughout normal connective tissue, where they are often situated adjacent to blood and lymphatic vessels, near or within nerve sheaths, and beneath epithelial surfaces that are exposed to environmental antigens such as the respiratory and GI tracts.[156,158] The c-kit receptor for stem-cell factor is present on mast cells, but absent from the majority of basophils.[158,159] The c-kit ligand, or stem-cell factor (SCF), is the main survival and developmental factor for mast cells, but other growth factors and cytokines such as IL-3, Il-4 and IL-9 are also supportive for mast cell development.[158] Mature mast cells do not circulate in the blood, although circulating mast cell progenitors have been described[141] and retain a limited proliferative capacity in the tissue compartment.[160] In contrast to monocytes and macrophages, a transformation between the circulating and tissue forms of basophils and mast cells has not been observed.

Mast cells can be categorized into several types in mice and humans. In mice, the different types can be distinguished by their main tissue distribution and the major type of proteoglycan in their granules (heparin-containing mast cells are predominantly connective tissue and serosal mast cells, whereas chondroitin sulphate-containing mast cells are associated with mucosal surfaces). In humans two major subsets are identified based on the their content of chymase and tryptase. Both contain tryptase, but a subset that is particularly low in chymase largely secretes cytokines and chemokines and does not degranulate as opposed to the chymase rich type.[154,159]

Mononuclear Phagocytes

The blood monocyte is derived from a bone marrow progenitor cell, the GMP, shared with the neutrophil, and undergoes differentiation through stages as monoblasts and promonocytes in the bone marrow. Monocytic differentiation of GMP is favored by a high level of the transcription factor PU.1 relative to C/EBPα, whereas the opposite drives granulocytic differention.[161-163] The transit time for monocytes in the marrow compartment is briefer than for neutrophils, and the mature monocyte is released into the circulation only 24 hours after the last mitosis (see Table 22-1).[164,165] Consequently, a relative monocytosis in peripheral blood commonly precedes the return of granulocytes during recovery from bone marrow aplasia or hypoplasia. Monocyte production and differentiation are regulated by IL-3, IL-6, GM-CSF, and the more lineage-specific cytokine M-CSF.[2,5-7,166]

The monocyte may spend several days in the intravascular compartment in either circulating or marginated pools.[167] Monocytes migrate into tissues and body cavities to participate in inflammatory processes as exudate macrophages and to replenish the resident tissue macrophage population, which has a relatively long life span. In patients receiving allogeneic bone marrow transplants, host tissue macrophages disappear gradually and are replaced by donor macrophages approximately 3 months after transplantation.[168] Recent studies in mice suggest that at least some tissue macrophages are derived from stem cells that migrate to tissues during fetal development and maintain the macrophage pools in situ,[169-171] provided these stem cells are not destroyed as occurs during allogeneic stem-cell transplantation as shown in mouse models.[172]

The circulating monocyte in Wright-stained blood smears is 10 to 18 μm in diameter with a convoluted surface, a grey-blue cytoplasm, and an indented or kidney-shaped, foamy nucleus. However, some monocytes can be as small as 7 μm in diameter and difficult to distinguish morphologically from lymphocytes. Like neutrophils, monocytes contain secretory vesicles[173] but only a single major class of granules with lysosomal characteristics,[174] of which subsets have been described based on content of transforming growth factor α (TGF-α).[175] Traditionally, two circulating populations of monocytes are identified by flow cytometry as either classical monocytes or the nonclassical monocytes. Classical monocytes have a high expression of CD14 (the LPS receptor) and a low expression of CD16 (the low-affinity immunoglobulin G [IgG] receptor), accounting for approximately 90% of circulating monocytes, whereas nonclassical monocytes have a high expression of CD16. An intermediate type, previously assigned to the nonclassical type, is now recognized as having high expression of CD14 and intermediate expression of CD16. These CD16 expressing types are in general seen as possible precursors of dendritic cells. The relative distribution among these subsets is not fixed and changes with exposure to growth factors and cytokines such as M-CSF and TNFα.[176,177]

After leaving the circulation, monocytes become larger and take on the appearance of tissue macrophages characteristic of the organ in which they reside. The macrophage nucleus is typically oval with more prominent nucleoli, and the cytoplasm stains blue because of an increase in RNA content. Monocytes and macrophages are distinguished histochemically by the presence of a fluoride-inhibitable nonspecific esterase and can be identified immunohistologically by a variety of monoclonal antibodies such as F4/80 in the mouse and anti-CD68 in human tissue.[178,179]

Monocytes and macrophages share many structural and functional features with neutrophils, and are capable of sensing chemotactic gradients, migrating to inflamed sites, ingesting microorganisms, and killing them using a variety of cytocidal products. However, compared to neutrophils, mononuclear phagocytes have a large and diverse developmental potential.[176,180,181] In addition to their protective function as phagocytic cells in host defense, mononuclear phagocytes play a central role in the adaptive immune response by presenting antigens to lymphocytes, elaborate growth factors and cytokines important for lymphocyte function, wound repair, and hematopoiesis, and participate in a variety of scavenger and homeostatic pathways.[180,182-184] Mononuclear phagocytes at inflammatory sites become "activated," displaying morphologic alterations and a variety of enhanced functions. These include a more pronounced ruffling of the plasma membrane and pseudopod formation, an increased capacity for adherence and migration to chemotactic factors, increased microbicidal and tumoricidal activity, and enhanced ability to release cytokines.[183-186]

Monocytes and tissue macrophages are considered to make up a "mononuclear-phagocyte system."[167] Resident tissue macrophages were formerly referred to as *histiocytes,* an imprecise and often loosely applied term. Tissue macrophages are widely distributed and perform specialized functions at portals of entry such as the pulmonary alveoli and in sterile sites such as the bone marrow.[180]

Spleen

Macrophages are distributed in all parts of the spleen, including the germinal centers where they are associated with lymphocytes. Splenic macrophages located in the red pulp and sinuses serve a clearance function, where a sluggish blood circulation maximizes the interaction between blood elements and the macrophages lining the sinus walls.[187]

Liver

The portal circulation percolates through a labyrinthine system, the spaces of Disse, before exiting via the hepatic venous system. This hepatic circulation, although less sluggish than that of the spleen, provides considerable contact between the blood and the resident liver macrophages, known as *Kupffer cells,* that reside within these vascular sinuses.

Lymph Nodes

As in the spleen, macrophages exist through all regions of peripheral lymph nodes. They are most abundant in the medullary zone close to efferent lymphatic and blood capillaries. This location is likely related to the important role macrophages play in the presentation of antigens to T lymphocytes.[182,188]

Lungs

Pulmonary macrophages reside both in the interstitium of alveolar sacs and free within the air spaces, where they participate in the clearance of inhaled microorganisms and particulate matter. The number of lung macrophages increases in many chronic pulmonary inflammatory disorders. Pulmonary macrophages are easily seen in lungs of smokers, where black inclusions mark the macrophage vacuoles.[189] Hemosiderin-laden alveolar macrophages can be indicative of recurrent pulmonary hemorrhage, such as in idiopathic hemosiderosis or Goodpasture syndrome. Gastric aspiration to detect ingested iron-laden macrophages is a useful test for these disorders.

Bone Marrow

Macrophages are found throughout the bone marrow cavity. They are particularly abundant within hematopoietic islands and on the walls of the marrow sinuses.[190] Bone marrow macrophages may have a clearance function in normal or pathologic states of ineffective hematopoiesis.[39,63,191] The clearance function of marrow macrophages is dramatically illustrated by the lysosomal storage diseases such as Gaucher disease.[192] Large inclusions build up within marrow macrophages (as well as hepatic and splenic macrophages) because of the inability of these cells to break down lysosomal contents.[193] Bone marrow macrophages also support hematopoiesis by modulating mesenchymal stem cells and osteoblasts to express retention signals, in particular CXCL12, for HSCs.[194-196]

Other Sites

Mononuclear phagocytes associated with lymphoid cells reside throughout the alimentary tract, particularly in the submucosal tissues and small intestinal villi. They are present as microglial cells in the central nervous system (CNS), where their numbers increase after injury as monocytes emigrate across the blood-brain barrier,[170,197] and they may contribute to the pathogenesis of the CNS manifestations of infection with the human immunodeficiency virus (HIV).[198] Mammary gland macrophages released into milk during lactation have been implicated as a potential source of postnatal transmission of the HIV virus.[199]

Dendritic Cells

Dendritic cells are specialized antigen-presenting cells with long cytoplasmic processes that are located in tissues throughout the body except for brain.[200,201] They develop from a progenitor common with monocyte progenitors, supported by GM-CSF. M-CSF induces monocytic differentiation, and Flt3 ligand induces differentiation into a dendritic cell progenitor that may leave the bone marrow and home to lymphatic tissue and nonlymphoid tissue throughout life. In contrast, Langerhans cells of the epidermis, which are also antigen presenting cells, are self sustained and localize to skin during embryonic development.[181,201,202] Some dendritic cells are also derived from the lymphoid lineage.[201,203] Antigen presentation by dendritic cells, which have a high density of MHC class II molecules, is a particularly potent stimulus for T-cell mediation of the primary immune response.[200,201,204] Plasmacytoid dendritic cells are a specialized population of dendritic cells, although derived from a shared precursor, that respond rapidly to viruses or nucleic-acid–containing complexes by secreting large amounts of type I interferon (IFN).[205,206] NETs have been linked to activation of plasmacytoid dendritic cells and the pathogenesis of lupus.[200,205-208]

Osteoclast

Osteoclasts are large, multinucleated mononuclear phagocytes that resorb mineralized cartilage and bone.[209,210] Rodent transplantation studies have shown that osteoclasts can be derived from granulocyte-macrophage progenitor cells.[211] Defects in osteoclast function result in osteopetrosis, a genetically heterogeneous group of disorders characterized by defective bone resorption.[212,213] The *Op/op* osteopetrotic mouse mutant lacks M-CSF, which results in deficiencies of both osteoclasts and tissue macrophages.[214] However, M-CSF levels and osteoclast numbers are normal in human infantile ("malignant") osteopetrosis,[215] an AR disorder with progressive obliteration of the marrow space.[212,216] This severe form of osteopetrosis is caused by mutations in genes encoding a vacuolar proton pump or the chloride channel 7.[217,218]

FUNCTION OF PHAGOCYTES

Phagocytic leukocytes play a central role in the acute phases of the inflammatory response, where they are rapidly mobilized into sites of tissue infection or injury and release an array of cytotoxic molecules to quickly eliminate the offending substance or microbe, as well as mediators that initiate an adaptive immune response. Phagocytes are also essential for normal repair of tissue injury, as evidenced by the impairment in wound healing in patients with deficits in leukocyte function or number.

The classic signs of the inflammatory response were described by the Roman writer Celsus as *"rubor et tumor, cum calore et delore,"* or, *"redness and swelling with heat and pain."*[219] However, it was not until the late nineteenth century that the cellular events associated with these signs were studied by Virchow and by Cohnheim.[219] The beneficial role of phagocytes in the inflammatory process for host defense and wound healing was championed by Metchnikov. He received a Nobel prize for his work,[219,220] much of which involved studies on the wandering ameboid mesenchymal cells of marine organisms like the larval starfish, for which he coined the term *phagocyte,* after the Greek word, *phagein*, "to eat."

In this section, the principle functions of granulocytes and mononuclear phagocytes in the inflammatory process are reviewed. Although these functions will be discussed as individual components, it is important to recognize that many occur either simultaneously or in rapid succession. An overview of early events in the inflammatory process and cross talk between different leukocyte populations is shown in Figure 22-2. Note that proinflammatory events that are critical for the response to tissue injury, and the effective elimination of microbial challenge also sets into motion the generation of

Figure 22-2 Early events in the response to infection accompanied by mild tissue injury. During the early inflammatory response, a variety of soluble inflammatory mediators are involved in crosstalk between different leukocyte populations and lead to their recruitment and activation. Multiple signals, generally requiring evidence of both injury and infection, are required before each population fully joins in to amplify the inflammatory process. Not shown are interactions among leukocytes, the endothelium, and the coagulation system; the generation of counter-regulatory signals that dampen the inflammatory response; and signals that regulate the subsequent transition to wound healing. *APC,* Antigen-presenting cell, *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *HMGB1,* high–molecular group box 1 protein; *HSP,* heat shock proteins; *PDG2,* prostaglandin G2; *TNF,* tumor necrosis factor. *(From Nathan C: Points of control in inflammation.* Nature *420:846–852, 2002.)*

counterregulatory signals leading to resolution of the inflammatory response.[221-224]

Humoral Mediators of the Inflammatory Response

The acute inflammatory response reflects an ongoing collaboration between tissue macrophages and mast cells, vascular endothelial cells, and circulating phagocytes.[222,225] The release of soluble inflammatory mediators is crucial for activating and coordinating this process. These molecules can be generated from plasma proteins (e.g., the complement-derived protein fragment C5a), secreted by endothelial cells or inflammatory leukocytes (e.g., lipid metabolites, histamine, cytokines, S100 proteins), derived from invading microbes (e.g., endotoxin or formylated chemotactic peptides), or released from damaged cells (e.g., heat shock proteins [HSPs], the nuclear protein high molecular–group box 1 protein [HMGB1]).[222,226-230]

The proinflammatory cytokines TNF-α and IL-1 have a broad range of activities in the acute inflammatory response.[83,231] Both IL-1 and TNF can cause fever and muscle breakdown and are involved in the cachexia associated with chronic infection and malignancy. The synthesis of acute phase reactants by the liver is induced by IL-6, whose synthesis and secretion is stimulated by IL-1. Proinflammatory cytokines also induce a proadhesive state on the surface of endothelium and increase the production of the chemotactic cytokines (chemokines). IFN-γ is another important proinflammatory mediator that enhances the responsiveness of phagocytes to inflammatory stimuli.[183,184,232] Counterbalancing the activities of these polypeptides are IL-4, IL-10, and TGF-β, which tend to down-regulate the acute inflammatory response.[233-235]

Lipid mediators play both proinflammatory and antiinflammatory roles.[221] As the inflammatory process progresses, a "class switch" is observed in neutrophils such that lipoxygenase activity induces production of antiinflammatory lipoxins instead of proinflammatory leukotrienes. In addition products of ω-3 unsaturated fatty acids, resolvins D1 and D2, are generated by neutrophils, and the related maresins are generated by efferocytosing macrophages.[236] These products inhibit neutrophil transmigration by downregulating surface proteins involved in transepithelial migration, by inducing nitric oxide (NO) production in endothelial cells, and by enhancing the production of antiinflammatory cytokines and inhibiting production of proinflammatory cytokines of macrophages and making them more apt for uptake of apoptotic neutrophils.[223,237]

Vasodilation and increased vascular permeability are two early responses to an inflammatory insult that are elicited in large part by products secreted by granulocytes and mononuclear phagocytes. Activated basophils and tissue mast cells release histamine, which leads to vasodilation of tissue arterioles and microvascular beds through H_1-type receptors.[238,239] The lipid metabolite platelet activating factor (PAF), which is secreted by activated macrophages, mast cells, and endothelial cells, induces platelet degranulation and the release of additional histamine and also serotonin, another vasoactive amine.[230,240] Prostaglandin E and other arachidonic acid metabolites secreted by activated neutrophils and macrophages are another group of potent vasodilators.[221,230] Finally, vasodilation can be triggered by the release of NO from endothelial and smooth muscle cells as well as perhaps from activated macrophages, which may be particularly important in the hypotension seen with gram-negative septicemia.[241,242] The increased vascular permeability that produces the edema of acute inflammation allows plasma proteins such as immunoglobulins and complement to enter tissues to promote phagocyte activation and opsonize microbes. Agents that increase vascular permeability include histamine, serotonin, PAF, and leukotrienes (LTs) C_4, D_4, and E_4.[240] Bradykinin, which is generated as the result of Hageman factor (factor XII) cleavage, also induces enhanced vascular permeability.

Chemokines, Small Lipids and Other Chemoattractants

A wide variety of chemoattractants for neutrophils and other circulating leukocytes are generated at sites of inflammation (Table 22-4).[96,243-245,246,247] These molecules are chemically diverse and are derived from many different sources in response to bacterial products and inflammatory mediators released as a result of tissue necrosis. This diversity provides a functional redundancy and ensures that leukocytes will be attracted to sites of injury or infection. In addition to their role as chemoattractants, the molecules listed in Table 22-4 induce the activation of many other phagocyte functions upon binding to their cognate cell-surface receptors. These include the upregulation and increased affinity of leukocyte integrin adhesion receptors to promote firm attachment to the endothelium, degranulation, and activation of the phagocyte respiratory burst. Many chemoattractants are secreted by activated phagocytes, which act as a positive feedback loop for additional recruitment and activation of inflammatory cells.

The phospholipid PAF, released by both activated phagocytes and endothelial cells, triggers platelet activation and granule release in addition to being a potent chemoattractant for neutrophils and eosinophils.[230,240] Activation of phagocytes also stimulates the phospholipase A_2-mediated cleavage of membrane phospholipids to generate arachidonic acid, which is then converted into a variety of eicosanoid metabolites, including the chemoattractant leukotriene B_4 (LTB_4).[221,229]

Chemokines (named for their combined *chemo*tactic and cyto*kine* properties) are a family of small (8 to 10 kDa) basic heparin-binding proteins that comprise an important group of phagocyte chemoattractants.[94,244,247] Chemokines were first discovered in the late 1980s as molecules that interact relatively specifically with subsets of inflammatory leukocytes and therefore help orchestrate the sequential influx of neutrophils, monocytes, and finally lymphocytes into an inflamed tissue site. Proteoglycans on endothelial cells or in the subendothelial matrix bind chemokines to produce locally high chemokine concentrations at an inflamed site.[243,248,249] As additional chemokines and their receptors have been identified, many other functions have emerged, including regulation of lymphoid homeostasis, hematopoiesis, and angiogenesis.[96,244] Of note, SDF-1 *(CXCl2)*, provides a key

retention signal for neutrophils in the marrow through its interaction with the CXCR4 receptor, and mutations in the *CXCR4* receptor account for the WHIM syndrome, an inherited neutropenia.[35,36]

Members of the chemokine family, which have a conserved structure containing two cysteine pairs, have been divided into two groups based on the disulfide sequence pattern. The CXC family, in which the first cysteine pair is separated by an intervening amino acid, include IL-8 *(CXCL8),* the growth-regulated oncogene (GRO) peptides (*CXCL1, 2,* and *3*), and neutrophil-activating protein 2 (NAP-2; *CXCL7*), which are all potent neutrophil activators and chemoattractants. The IL-8 and GRO chemokines are secreted by phagocytes and mesenchymal cells (including endothelial cells) in response to inflammatory mediators such as IL-1 and TNF.[96] Fractalkine *(CX$_3$CL1)* is unique in having three intervening amino acids between the first two cysteine residues. In addition, rather than being soluble, fractalkine is expressed on the cell surface, because it is linked via a mucinlike stalk to a transmembrane domain.[250] The other major family of chemokines is called the CC *family,* because the first two cysteines are adjacent to each other. CC chemokines include two important inducers of mononuclear phagocyte migration, monocyte chemotactic protein 1 (MCP-1; *CCL2*) and RANTES *(CCL5).*[251-253] MCP-1 is produced by a wide variety of cells, whereas RANTES is secreted by macrophages and eosinophils.[96] RANTES is chemotactic for eosinophils, basophils, and memory T cells as well as monocytes,[252] and both MCP-1 and RANTES induce histamine release from basophils.[238,239,252]

Despite the diverse chemical structures of phagocyte chemoattractants listed in Table 22-4, the corresponding receptors all belong to the seven-transmembrane–spanning receptor (7-TMR) family, also known as *heptahelical* or *serpentine receptors,* that are coupled to heterotrimeric G proteins.[254,255] For chemokines, more than six receptors for CXC chemokines and ten receptors for CC chemokines have been identified.[94,244] Most chemokines bind to more than one receptor, and most chemokine receptors, particularly those for CC chemokines, recognize more than one chemokine. Neutrophils, monocyte/macrophages, eosinophils, basophils, dendritic cells, lymphocytes, and T cells each express a distinctive subset of chemokine receptors. According to one model, specific receptors are used sequentially in successive gradients of chemoattractants. Some transmit desensitizing, rather than activating, signals or even fail to signal and act instead as "decoy" receptors to downregulate inflammatory reactions.[244] Of note, a number of chemokine receptors are coreceptors for HIV-1, including *CCR5* and *CCR3,* whose ligands include RANTES, and *CXCR4,* the major receptor for stromal cell–derived factor 1 (SDF-1), which is a chemoattractant for T lymphocytes, CD34+ hematopoietic progenitor cells, and neutrophils.[35,96]

The signaling through 7-TMR has proven much more complicated (and powerful) than the original signaling mediated via associated heterotrimeric G proteins, which bind to specific intracellular domains of the receptor.[256] Ligand binding to the receptor promotes the exchange of GTP for guanosine diphosphate (GDP) bound to the G protein α subunit, which in turns leads to the dissociation of the β-γ subunits and their interaction with downstream signaling effectors. In addition, 7-TMR associates with β arrestins and signals through these in a G-protein independent way.[257,258] Finally, 7-TMR may transactivate tyrosine kinase growth factor receptors.[259] Signals generated from 7-TMR activate enzymes that catalyze the production of important phospholipid second messengers at the cell membrane.[260]

Adhesion and Migration into Tissues

The discovery that leukocytes migrate from the bloodstream into extravascular sites of inflammation, described by Cohnheim in 1867, was a major milestone in the conceptualization of the inflammatory process.[219] Cohnheim, who used intravital microscopy to study the microvasculature in the frog tongue and mesentery after tissue injury, also first proposed that inflammatory stimuli induce a molecular change in the blood vessel wall that promoted the increased adherence of leukocytes, a concept that was finally proven a century later.

To move from the bloodstream into inflamed sites, leukocytes must attach to the vascular endothelium, migrate between adjacent endothelial cells in a process referred to as *diapedesis,* and penetrate the basement membrane. The molecular mechanisms underlying these events involve a series of sequential adhesive interactions between chemoattractant-activated leukocytes and endothelial cells that are activated by inflammatory mediators (Fig. 22-3).[75,117,243,261-265]

Leukocyte Adhesion and Migration into Tissues

The initial step in emigration from postcapillary venules is a low-affinity interaction between the neutrophil and the endothelium that is often referred to as *rolling* because of its appearance in intravital microscopy. This transient adherence, also called *tethering,* is mediated by the upregulation of selectin expression on endothelial cells.[266] The selectin family of adhesion molecules are membrane-spanning glycoproteins (Fig. 22-4) that bind

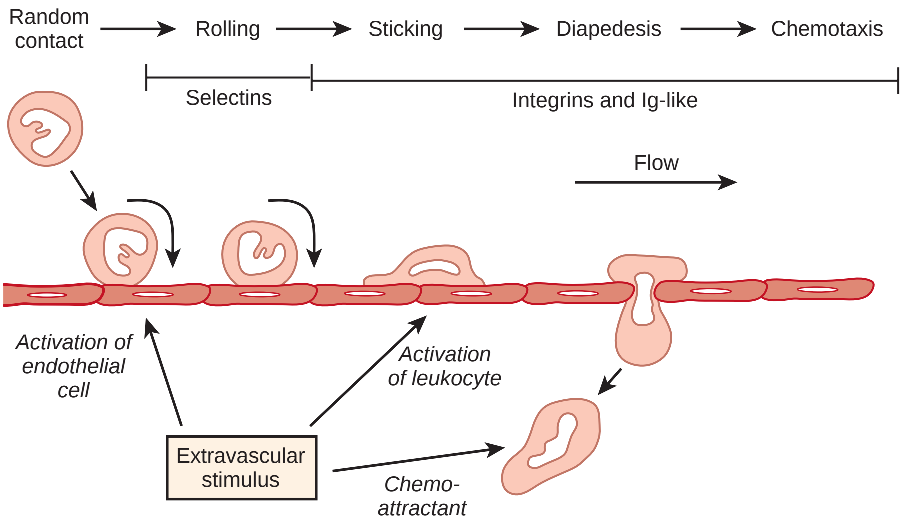

Figure 22-3 Adhesive interactions during phagocyte emigration. Under conditions of flow within postcapillary venules, leukocytes are first observed to roll along the endothelium adjacent to the extravascular site of inflammation. Subsequently, some of the rolling leukocytes adhere firmly, pass between endothelial cells by diapedesis, and then migrate into subendothelial tissue. Leukocyte rolling is mediated by multiple low-affinity interactions between selectin receptors and carbohydrate counter-receptors, and firm adhesion and diapedesis are largely mediated by integrin and Ig-like adhesion proteins. Chemokines or other chemoattractants are important for both upregulating the cell surface expression of leukocyte integrins and triggering inside-out signaling to increase their avidity for endothelial ligands. *(Modified from Carlos TM, Harlan JM: Leukocyte-endothelial adhesion molecules.* Blood *84:2068–2101, 1994.)*

to fucosylated structures such as Lewis X (Galβ1→4 [Fucα1→3] GlcNac→R), Sialyl-Lewis X, and other specific carbohydrates.[262,264,266,267] P-selectin is important for the initial steps of neutrophil adhesion to the endothelium and is stored in the Weibel-Palade bodies and α granules of endothelial cells and platelets, respectively. Upon endothelial cell activation by histamine, thrombin, and other inflammatory molecules, these cytoplasmic storage granules fuse with the cell membrane to rapidly increase the surface expression of P-selectin. E-selectin is expressed on endothelial cells at low levels, but it is upregulated by transcriptional activation and *de novo* protein synthesis in response to inflammatory cytokines.[268] E-selectin binds to three different ligands on neutrophils: P-selectin glycoprotein ligand (PSGL) 1, E-selectin ligand (ESL) 1, and CD44.[269] These ligands allow endothelial cells to capture neutrophils by mediating tethering, rolling, and slowing of neutrophil velocity, respectively. L-selectin is expressed constitutively on the surface of neutrophils, mononuclear phagocytes, and lymphocytes and is shed within minutes of leukocyte activation by a proteolytic cleavage event near the external membrane surface insertion site.[270,271] Circulating L-selectin may modulate leukocyte adhesion during inflammation.[272] PSGL-1 is constitutively expressed on the tip of microvilli on the neutrophil surface and remains associated during activation but moves to the uropod when the neutrophil polarizes.[264,273]

Rolling neutrophils can detach and return to the circulation. Others will come to a halt and within seconds adopt a flattened, adherent morphology and attach firmly to the vessel wall.[262] This firm attachment appears in large part to be mediated by leukocyte integrin adhesion receptors binding to intracellular adhesion molecules (ICAMs) on the endothelium.[262,263] In addition, complement fragments are found on the endothelial surface at inflamed sites and may also function as integrin binding sites. Leukocyte activation by chemoattractants and other inflammatory mediators is critical to the development of these strong adhesive interactions, because it leads to the upregulation of the number and avidity of cell-surface integrins (“inside-out signaling”).[274,275] Exposure to locally high concentrations of chemoattractants may be enhanced by selectin-mediated tethering and by the retention of chemokines on extracellular matrix.[248,249]

The integrins are a large family of adhesion proteins that are glycosylated heterodimers of a noncovalently linked α chain and β chain and are classified into subfamilies according to the type of β subunit.[262,263] Many integrins mediate attachment to extracellular matrices by serving as receptors for matrix proteins. Others are involved in hemostasis, such as glycoprotein IIb/IIIa on platelets. Neutrophil β_2 and β_1 integrins appear to be involved in regulating neutrophil retention and release, respectively, from the bone marrow storage pool into the circulation.[35]

The leukocyte β_2 integrins (Fig. 22-5) play a critical role in mediating adhesive interactions in inflammation, including the attachment of leukocytes to endothelial cells and are also opsonic receptors for complement fragment C3bi-coated particles. There are four different leukocyte β_2 integrins, each having a common 95 kDa β subunit (CD18) but different α subunits, CD11a (177 kDa), CD11b (165 kDa), CD11c (150 kDa), and CD11d (160kDa) (see Fig. 22-5). Lymphocyte function antigen 1 (LFA-1) is expressed on the surface of all leukocytes, including lymphocytes. Mac-1 and p150,95 are

expressed by granulocytes, mononuclear phagocytes, some activated T lymphocytes, and large granular lymphocytes.[262,263] Mac-1 is the most prominent β_2 integrin on neutrophils, whereas $\alpha_d\beta_2$ is expressed particularly in tissue macrophages. Mutations in the common β_2 subunit result in an inherited defect in phagocyte function, leukocyte adhesion deficiency type I (LAD I) as discussed in a later section. All β_2 integrins are absent in LAD I, indicating that the stability of each α subunit requires association with the β_2 chain. The β_2 subunit has a large, glycosylated extracellular domain, a single transmembrane-spanning domain, and a short cytoplasmic tail.[276] The extracellular domain has two regions that are conserved among other β subunits.[274] There are four cysteine-rich tandem repeats that appear to be important for the tertiary structure of the β subunit. Another conserved region, located near the N-terminus, is critical for maintenance of the α/β heterodimer and may also bind divalent cations. The α subunit is also a glycosylated integral membrane protein with a single membrane-spanning segment and a short cytoplasmic tail. The external domain contains three divalent cation-binding motifs that must be occupied for ligand binding to occur. A second important extracellular domain, the I domain (for *inserted* or *interactive* domain), can coordinate divalent cations and is also thought to be involved in ligand binding. The intracellular domain of the α subunit includes a conserved sequence that is critical for the modulation of integrin avidity (see "Leukocyte Adhesion Deficiency").[277]

Although β_2 integrins are constitutively expressed on the neutrophil cell surface, a large pool of Mac-1 is stored in intracellular secretory vesicles (see Table 22-2). These vesicles are rapidly mobilized upon neutrophil activation by chemoattractants and fuse with the membrane to increase the cell surface expression of β_2 integrins by about tenfold.[243,278] Signaling through chemoattractant receptors also markedly increases the avidity of β_2 integrins for their ligands, which plays an even more important role in rapidly upregulating integrin activity and promoting firm attachment to the blood vessel wall.[262,263,274] Integrins on inactivated cells have a bent position that does not allow ligand binding. Signals generated from 7-TMRs recruit talins to the cytoplasmic part of the integrin β chains, twisting the α and β chains apart and tethering the integrins to the actin cytoskeleton. This is assisted by actin-binding protein (ABP) 1[279] and by the protein Kindlin 3, which is only expressed in cells of hematopoietic origin. This changes the conformation of the extracellular parts of the αβ heterodimer to an extended form, now capable of ligand binding and hence also of transducing signals from outside in.[275] Defects in Kindlin 3 results in LAD III (see "Leukocyte Adhesion Deficiency Type III").[274,280-285] Ligand binding to integrins results in clustering of the integrins and the transmembrane calcium channel Orai1 that mediates store operated calcium entry[286] and activation of tyrosine kinase and other signaling cascades,[287] which in addition to mediating adhesion, provide important costimulatory signals to enhance migration, respiratory burst, Fcγ-mediated phagocytosis, and degranulation.

The major counterreceptors for the β_2 integrins are the ICAMs (Fig. 22-6), which are members of the immunoglobulin superfamily.[262,263,274] These transmembrane proteins contain anywhere from two to six immunoglobulin

	ICAM1	ICAM2	ICAM3

domains and are present on endothelial cells, T cells, and a variety of other cell types. ICAM-1 and ICAM-2 are of particular importance in mediating binding of neutrophils and other leukocytes to the endothelium. Endothelial cell expression of ICAM-1 increases in response to inflammatory cytokines, which promotes increased cell–cell interactions with leukocytes at inflamed sites. VCAM-1 is another immunoglobulin superfamily member expressed on endothelial cells that is inducible by cytokines.[263,288] VCAM-1 is the counter-receptor for the β_1 integrin, VLA-4, and appears to be important in promoting the adherence of monocytes and eosinophils during inflammation. The β_2 integrin Mac-1 also has an important role as an opsonic receptor for the complement fragment, C3bi (see "Recognition, Opsonization, and Phagocytosis").

Although leukocyte β_2 integrin-mediated adhesion is clearly important for neutrophil recruitment from the systemic microvasculature into inflammatory sites, neutrophil emigration out of the pulmonary circulation can also be mediated by alternative pathways, depending on the inflammatory stimulus.[289] Whether the alternative pathway in pulmonary capillaries, which are in close proximity to the pulmonary epithelial cells, involves selectins or other adhesion molecules remains to be defined. TREM-1 is essential for pulmonary transepithelial migration of neutrophils.[290]

The final steps in emigration of neutrophils from the blood vessel lumen into inflamed tissue involves squeezing between adjacent endothelial cells (diapedesis) and penetrating the basement membrane (see Fig. 22-3). The presence of a chemotactic gradient is required to induce the directional migration of neutrophils.[248,291,292] Adhesive interactions between the β_2 integrins and endothelial cell ICAM-1 are essential for neutrophil diapedesis, whereas VCAM-1 and E-selectin can mediate the transmigration of monocytes and eosinophils.[117,261] Junctional adhesion molecule (JAM) 1, an immunoglobulin superfamily protein that is expressed at tight junctions of resting endothelial cells and epithelial cells, facilitates leukocyte transmigration via binding to LFA-1 (CD11a/CD18).[293] The tight junction between endothelial cells is weakened by loss of paxillin and focal adhesion kinase in proximity to migrating neutrophils.[294,295] Transendothelial migration of neutrophils is also dependent on homologous binding between neutrophil and endothelial cell platelet–endothelial cell adhesion molecule (PECAM) 1 (CD31), another immunoglobulin superfamily member expressed on the surface of leukocytes, platelets, and endothelial cells, where it is localized at the junctions between cells.[296,297] Signals from ICAM-1 induce vascular permeability,[298] activate PECAM-1 for enhanced adhesivity, and support of neutrophil transendothelial migration.[299-301] The JAM-C expressed by endothelial cells seems important for directing neutrophil migration into tissues and inhibiting migration in the reverse direction.[302] Migrating neutrophils induce increases in endothelial intracellular calcium levels and changes in actin cytoskeleton that facilitates transmigration.[303,304] To find gaps between pericytes sheathing endothelial cells, neutrophils use ICAM-1 to crawl along pericyte extensions, which further guide their migration into tissues.[44-46] Finally, chemoattractant-induced neutrophil degranulation results in the release of digestive enzymes, including collagenase, elastase, and gelatinase, which may facilitate basement membrane penetration.[68,305,306]

Chemotaxis

Chemotaxis is the directional movement of a cell along a concentration gradient.[86,266,307-310] Defects in neutrophil cellular motility or other steps in chemotaxis can result in decreased resistance to bacterial and fungal infections, as discussed later in this chapter. Cells respond to a chemotactic gradient by sensing constantly across their surface, and bound chemotactic receptors are continuously internalized. A migrating neutrophil has a polarized appearance, extending pseudopodia or lamellipodia, thin structures rich in actin filaments and lacking intracellular organelles, at the leading edge.[308,311,312] The pseudopods appear to glide forward, pulling the cell body behind them. The nucleus tends to remain at the posterior half of the moving leukocyte. Migration also requires formation of a uropod at the "tail" of the leukocyte, which detaches from the underlying matrix and retracts the rear of the cell as it moves forward.[313] Rho GTPases play an important role in establishing chemoattractant-induced polarization and migration.[82,314] Ly49Q, a surface-expressed MHC I–associated receptor is associated with the SH2 domain–containing protein tyrosine phosphatase (SHP) 1 phosphatase in nonpolarized neutrophils but exchanges SHP-1 with SHP-2 in activated cells, which results in reorganization of lipid rafts and polarization.[315]

Neutrophil movement is dependent on the dynamic assembly and disassembly of filamentous actin, which is coordinated by various ABPs whose activity is regulated by intracellular signaling molecules.[307,309,316-318] Actin can exist as either a soluble monomer (globular actin) or in needlelike helical filaments (filamentous actin). Actin filaments align spontaneously in parallel bundles, but in the cell are organized into a branching network because of the presence of actin filament cross-linkers such as ABP.[319] Agonists acting via receptors on the cell membrane trigger the generation of second messengers, which interact with ABPs to control dynamic local cycles of filamentous actin assembly.[308] The Rho GTPases (Cdc42 and Rac) are important regulators of actin remodeling and are activated by ligand binding to chemoattractant receptors.[80,314,320,321] Cdc42 activates proteins of the Wiskott-Aldrich syndrome protein (WASP) family, which then bind to a complex of seven proteins known as the Arp2/3 complex to nucleate assembly of new actin filaments at the leading edge of migrating cells.[312,316]

During pseudopod extension in chemoattractant-activated neutrophils, new actin polymerization occurs at the site of membrane protrusion while the filamentous actin in the rear of the cell disassembles.[309,310,322] How actin assembly–disassembly results in membrane extension and formation of pseudopodia is not fully understood, but it may involve localized changes in osmotic pressure caused by changes in actin polymerization.[308,311] Membrane movement and retraction at the rear of the cell is mediated in part by Rho GTPase-regulated contractile proteins such as myosin 1.[309,323,324]

Recognition, Opsonization, and Phagocytosis

The recognition, ingestion, and disposal of microbes, foreign particulate matter, and damaged cells constitutes a major aspect of phagocyte function. To facilitate their recognition by phagocytes, these targets are coated with serum opsonins (the term *opsonin* is from Greek, *to prepare for dining*) that include proteolytic fragments derived from the complement cascade as well as specific immunoglobulins. The key humoral opsonins are the proteolytic cleavage products of C3 (C3b and C3bi), which can be generated in the absence of specific immunity by the alternative and mannose-binding lectin pathways (see later), and the opsonic antibodies, IgM, IgG_1, and IgG_3. Targets are opsonized by the deposition of C3b and C3bi or of IgG onto their surfaces via the specific (Fab) portion of the antibody. Antibacterial IgM antibodies, although not opsonic by themselves, play an important role in phagocytosis by activating complement. Opsonins are recognized by phagocyte cell-surface glycoprotein receptors for immunoglobulin and C3 cleavage products, as described later. Inherited deficiencies of opsonization can result in increased susceptibility to bacterial infections, as discussed in "Disorders of Chemotaxis." In contrast, primary defects in phagocyte receptors for these opsonins appear to be an uncommon cause of recurrent infections.[325]

Phagocytes also have cell surface receptors capable of recognizing targets even in the absence of opsonins. These members of the pattern recognition receptor (PRR) family recognize broad classes of macromolecules.[77,79,80,182,326] PRRs recognize molecular signatures unique to microbes, known as PAMPs (such as LPS or molecules released from damaged or stressed tissue known as DAMPs), such as adenosine triphosphate, as discussed previously in this section. PRRs include scavenger receptors, which have broad binding specificity for polyanionic ligands and participate in the clearance of diverse materials, including modified low-density lipoprotein (LDL) and apoptotic cells.[182] The mannose receptor recognizes carbohydrate structures present in a range of bacteria, fungi, virus-infected cells, and parasites whereas the β-glucan receptor (dectin-1) binds to β-glucan structures in zymosan and other yeast-derived particles. Mammalian TLRs are an important group in the PRR family.[78,79,89,327] At least 12 different TLRs have been described, which recognize conserved peptide, lipid, carbohydrate, and nucleic-acid structures expressed by different groups of microbes. For example, peptidoglycan and LPS are PAMPs associated with gram-positive and gram-negative bacteria and are recognized by TLR-2 and TLR-4, respectively. Binding to PRRs, which often occurs in a combinatorial fashion, activates an array of proinflammatory responses including expression of proinflammatory cytokines and release of oxidants and reactive nitrogen intermediates. TLR signaling activates the nuclear factor κB (NF-κB)– and IFN-regulatory factor (IRF)–dependent pathways, and genetic defects in the protein that couples TLRs to NF-κB lead to recurrent bacterial infections.[328] Some PRRs also trigger phagocytosis, including the mannose receptor, scavenger receptors, and β-glucan receptor.[326]

In addition to cell surface PRRs, soluble PRRs present in serum or tissues serve important roles in alerting phagocytes to the presence of microbes.[329,330] These include the collectins (calcium-dependent lectins) that bind to oligosaccharide or lipid moieties of microorganisms to enhance their opsonization and efficiently activate phagocytes. Members of the collectin family include the lung alveolar surfactant proteins A and D and the mannose-binding lectin (MBL), also known as mannose binding protein.[330-332] The binding of MBL to mannose residues initiates a third pathway of complement activation (in addition to the classical and alternative pathways) by interacting with the MBL-associated serine proteases (MASPs) 1, 2, and 3, which generates opsonic C3 fragments.[329,333] MBL can also function itself as an opsonin for promoting uptake by the CR1 complement receptor.[330,333] Ficolins 1, 2, and 3 are other soluble PRRs that are capable of recruiting MASPs.[334-336] Pentraxin 3 is a soluble pattern recognition molecule stored in neutrophil-specific granules and important for humoral innate immunity.[337]

Inflammasomes

Signaling through the membrane-bound PRRs in the previous paragraph generally leads to activation of the NF-κB pathway or IRF and production of proinflammatory cytokines, in particular IL-1β and IL-18 and type-1 IFNs, respectively.[87] IL-1β and IL-18 are both without signal peptides and stored in the cytosol as proforms, but when processed by proteases, which in turn are activated by inflammasomes, these cytosolic cytokines are secreted from the cells by unconventional secretion mechanisms. IL-1β and IL-18 play a major role in activation of several steps of the inflammatory process, including endothelial cell and B-cell activation. Inflammasomes are structures that are assembled from preformed subunits in the cytosol in response to a variety of stimuli, such as signaling through cell surface (as discussed) or intracellular PRR such as the nucleotide-binding oligomerization domain–like receptors (NLRs) and retinoic acid–inducible gene 1–like receptor. Depending on the activating stimulus, different subunits become engaged in formation of the macromolecular complex known as an inflammasome and activate procaspase 1 to process the cytosolic proIL-1β and proIL-18 to the mature forms for secretion.[89,338-340] A major cytosolic protein of neutrophils, pyrin, forms part of some inflammasomes, and mutations in the pyrin gene *MEVF* cause the inflammatory condition known as familial Mediterranean fever.[341]

Complement Receptors

The activation of complement C3 to generate the cleavage fragments C3b and C3bi is the dominant source of opsonins in the absence of antibodies. Four C3 fragment receptors have been described on phagocytic leukocytes (Table 22-5). The human phagocyte C3b receptor (CR1; CD35) is a high–molecular-weight, single-subunit glycoprotein that shows a substantial heterogeneity in size because of the presence of four distinct alleles in the human population that encode proteins ranging in size

from 160 to 250 kDa. CR1 is responsible for the binding of C3b-opsonized particles and for initiating their ingestion.[333,342] CR1 also recognizes microbes opsonized with MBL.[330,331,333] The other major opsonic receptor, CR3, recognizes particles opsonized with C3bi. This receptor is the same as the β_2 integrin Mac-1 (CD11b/CD18) discussed in detail in an earlier section (see Fig. 22-5). Binding of C3bi-opsonized particles to Mac-1 triggers both phagocytosis and, in neutrophils, the respiratory burst. The CR4 receptor is the same as the β_2 integrin CD11c/CD18 and, on macrophages, can also initiate phagocytosis of C3bi-coated targets. Finally, a newly discovered receptor that binds the complement fragments C3b and C3bi, termed *complement receptor of the immunoglobulin superfamily (CRIg)* is expressed primarily in resident macrophages of the liver (Kupffer cells).[343] CRIg appears to play a critical role in mediating phagocytosis and clearance of C3 fragment-opsonized bacteria from the circulation, at least in mice.[343]

Immunoglobulin Receptors

Immunoglobulins are recognized by Fc receptors (FcRs), which are members of the immunoglobulin gene superfamily. FcRs bind to the "constant domain" of the antibody molecule, these being specific to each class of immunoglobulins (IgA, IgE, IgG, and IgM).[325,344,345] The most important from the standpoint of microbial opsonization are those FcRs that recognize IgG (FCγRs) (Table 22-6). The FcγRs include three distinct classes, FcγRI, FcγRII, and FcγRIII, which are encoded by at least eight genes that have evolved through gene duplication and alternative splicing, although not all give rise to detectable mRNA and/or protein.[346] The low-affinity FcγR genes (FcγRII and III families) and two of the genes for the high-affinity IgE receptor are clustered on chromosome 1q22. The high-affinity FcγRs map to other sites on chromosome 1.

Except for FcγRIIIb, which is anchored in the membrane by a GPI moiety, the FcγR proteins have a single transmembrane domain. FcγRI and FcγRIIIa exist as oligomeric complexes with γ (in phagocytes) or ζ (in lymphocytes) chains that are important both for their stable expression and signaling functions.[346] These accessory chains contain YXXL ITAM motifs that become tyrosine phosphorylated upon receptor cross-linking to initiate downstream signaling cascades.[325,344,345] The cytoplasmic tail of the FcγRIIa receptor contains variant ITAM motifs, and hence this receptor does not require accessory chains for its function. There is no murine equivalent to the FcγRIIa receptor.[345] The GPI-linked FcγRIIIb receptor must be co-ligated to either FcγRIIa or the β_2 integrin CR3 (Mac-1) to initiate signaling functions upon ligation.[325,344,345] FcγRIIb receptors, expressed on monocyte/macrophages, mast cells, and lymphocytes, contain ITIM sequences and instead inhibit cellular activation upon immunoglobulin cross-linking.[344,345]

Each FcγR is expressed at different levels, depending on the type of phagocytic cell (see Table 22-6), and some FcγRII and FcγRIII family members are also expressed on lymphocytes, platelets, thymocytes, natural killer (NK) cells, and mast cells.[345,346] The FcγR1 class includes the products of three highly homologous genes, denoted A, B, and C, although the protein products of the latter two have not been detected in vivo. The FcγR1a receptors are expressed by monocytes and neutrophils or eosinophils stimulated by IFN-γ or G-CSF and have a high affinity for monomeric IgG.[325,344,345] Members of the FcγRII and FcγRIII families have a low affinity for monomeric IgG but a high affinity for clusters of IgG (e.g., several antibodies bound to the same particle) and immune complexes. Only neutrophils and IFN-γ–stimulated eosinophils appear to express FcγRIIIb, and polymorphisms in this receptor correspond to the serologically defined NA1/NA2 antigen system, which is a common antibody target in alloimmune and autoimmune neutropenia (AIN).[347,348] Polymorphisms in FcγRIIa, FcγRIIIa, and FcγRIIIb are associated with an increased incidence or severity of various autoimmune or infectious diseases.[349] For example, the 131H allele of FcγRIIa, which is the only FcγR that mediates efficient phagocytosis of

IgG$_2$-opsonized bacteria, has been linked to a lower incidence of infections with encapsulated bacteria.[325]

Cross-linking of FcγRs can trigger a wide range of functional responses, including phagocytosis of IgG-coated microbes, blood cells, or tumor cells; ingestion of immune complexes; release of inflammatory mediators; activation of the respiratory burst; and antibody-dependent cellular cytotoxicity (ADCC). The relative roles of different phagocyte FcγR classes have not been clearly delineated, although all can function as receptors for opsonized particles or immune complexes. Binding of IgG to FcγRI and FcγRIIa activates the respiratory burst, whereas secretion of granular contents is a prominent response upon binding to FcγRII and FcγRIIIb.[325] Although the ligand-binding domains of different FcγRs all bind IgG, the specificity of the cellular response may be governed by the unique transmembrane and cytoplasmic domains of a particular FcR subtype.[344,345]

Ligation and cross-linking of FcγRs initiates a cascade of biochemical signals that are initiated by activation of nonreceptor protein-tyrosine kinases of the Src family, which phosphorylate ITAM motifs in the FcγR chain and in FcγRIIa to recruit and activate the Syk tyrosine kinase and further amplify ITAM phosphorylation.[83,350,351] Subsequent activation of several parallel pathways, including activation of PLC, PI3K, and MAP kinase (MAPK)-related pathways, and other targets leads to various cellular responses, including actin and membrane remodeling for particle ingestion, NADPH oxidase activation, and cytokine release. The DAP12 adaptor that normally potentiates these activating signaling pathways may signal for FcR and TLRs on macrophages that express TREM-2.[352]

The opsonization of microbes with secretory IgA antibodies is likely to be important in the clearance of microbes from the mucosal surfaces of the respiratory, GI, and urogenital tracts. Neutrophils and monocytes have an FcR for IgA (FcαR) that has close structural similarities with other members of the FcR family.[353] Ligation of the phagocyte FcαR can trigger phagocytosis, degranulation, and superoxide release.[354,355] IgE antibodies can activate eosinophils and mast cells through the high-affinity FcεRI receptors.

Phagocytosis

Engagement of any of the opsonic receptors initiates phagocytosis of an opsonized particle to form a phagocytic vacuole that encloses the particle.[356,357] The molecular details of this process are incompletely understood, but they involve membrane remodeling and the regulated assembly and disassembly of the actin cytoskeleton in a fashion analogous to the mechanisms that result in cell movement when chemotactic receptors are engaged. FcγR-mediated phagocytosis triggers the extension of long pseudopodia that attach in a zipperlike fashion around the particle and then fuse to form the phagosome, which is then drawn into the cell.[350,351] In contrast, complement-opsonized particles attach to the cell surface only at limited points and "sink" into the cytoplasm in the absence of any pseudopod extension.[351] These morphologic differences are associated with differences in the underlying biochemical pathways. phagocytosis is sensitive to inhibitors of tyrosine kinases and requires the Rac and Cdc42 GTPases, whereas CR3-mediated phagocytosis is dependent upon protein kinase C and the Rho GTPase.

Microorganisms can also enter phagocytes by nonopsonic routes that enable them to evade the cytocidal weapons that are otherwise activated upon phagocytosis. For example, after binding to the macrophage cell surface, *Salmonella typhimurium* induces extensive membrane ruffling that leads to internalization of the bacterium into a macropinosome or "spacious phagosome."[358] *Legionella pneumophila* attachment to macrophages induces the formation of a pseudopod that spirals around the bacterium to form a "coiling phagosome" that does not acidify or fuse with lysosomes.[358]

Cytocidal and Digestive Activity

The binding of ligands to phagocyte chemoattractant and opsonic receptors ultimately leads to the mobilization of phagocyte granules that contain cytotoxic and hydrolytic proteins and to the activation of enzymatic reactions that generate toxic oxygen metabolites (Fig. 22-7). These complementary processes are designed to modify or destroy the inciting object and are often classified as oxygen-independent and oxygen-dependent pathways.

Neutrophil granules are secretory organelles that can be divided into four general classes, as discussed in "Neutrophil Granule Biosynthesis and Classification" (see Table 22-2). Degranulation (also referred to as *exocytosis* or *mobilization*), the fusion of granule membranes with the plasma or phagosome membrane, results in the transfer of granule membrane constituents to a new membrane compartment and the discharge of the granule contents into the extracellular fluid or phagocytic vacuole. Microtubules and microfilaments are involved in granule translocation. Munc13-4, a regulator of vesicle trafficking, is essential for the recruitment of granule membranes to the surface and to the phagosomal membrane.[359] Degranulation is triggered by increases in calcium concentration when neutrophils are activated through chemoattractant and other receptors. Different neutrophil granule populations have marked differences between expression of vesicle-associated membrane protein 2 (VAMP-2), a fusogenic protein involved in exocytosis, which is highest in secretory vesicles, less in gelatinase granules, and still lower in specific granules.[61] Thus different granule classes vary in their responsiveness to calcium, which leads to the mobilization of different granule classes depending on the calcium concentration, which, in turn is proportional to the concentration of the chemoattractant or other activating signal.[51,68,360] Secretory vesicles, whose membranes are storage pools for β_2-integrin–adhesion proteins and other receptors, are mobilized with relatively low concentrations of calcium. The fusion of secretory vesicles with the plasma membranes provides a rapid way of upregulating the cell surface expression of these receptors along with MMP-25, another membrane constituent of secretory vesicles. Gelatinase (tertiary) granules are also easily mobilized for exocytosis at the cell surface to release the gelatinase (MMP-9). These metalloproteases are stored as inactive proforms and become activated by proteolysis after exocytosis to facilitate the breakdown of extracellular matrix during the early phases of neutrophil migration.[305] At the opposite end of the spectrum, azurophil (primary) granules, which contain cytotoxic proteins and hydrolytic enzymes, undergo only limited exocytosis, fusing primarily with phagocytic vacuoles to deliver their contents into a sequestered compartment.

Monocytes and macrophages do not have populations of cytoplasmic storage granules equivalent to those found in neutrophils. Instead, internalized phagosomes fuse sequentially with endocytic vesicles, and subsequently lysosomes, to form a phagolysosome, which has a highly acidic interior rich in hydrolases.[174,350,351]

Certain microorganisms can become intracellular parasites, because they have developed mechanisms to prevent granule fusion with the phagocytic vacuole or otherwise evade the phagocyte digestive and oxidative armamentarium. For example, although mycobacteria exist intracellularly within a phagosome, they produce compounds that inhibit their fusion with lysosomes.[361] *L. pneumophila* and *Toxoplasma* may inhibit acidification and lysosomal fusion.[358] Virulent strains of *Salmonella* engulfed by macrophages produce compounds that prevent translocation of the respiratory burst oxidase to the phagosomal membrane.[362] *Listeria monocytogenes* escapes from the phagocytic vacuole altogether to avoid attack by lysosomal products and can survive in the cytoplasm of relatively quiescent macrophages and hepatocytes.[358] *Yersinia,* group A streptococci, *Helicobacter, Ehrlichia,* and *Francisella* are examples of microbes that have developed similar strategies to survive in neutrophils.[363]

In addition to delivering their antimicrobial granule contents to the interior of phagosomes, dying neutrophils are also capable of extruding weblike extracellular structures, NETs, composed of chromatin and granule proteins that can bind to microbes and may facilitate their killing.[49,50] Formation of NETs appears to involve a novel process of cell death that in some cases is dependent on oxidants generated from the neutrophil NADPH oxidase.[364] Since the discovery of this process, the molecular mechanisms of this process are emerging. It appears that intracellular liberation of elastase from azurophil granules, formation of hypochlorous acid, and decitrullination of histones to loosen the nucleosomes all play a role.[365-370] Experimentally, several agents are used to induce NETs, phorbol myristate acetate being the most common. Not all stimuli induce NETs by the same mechanism and induction by bacteria or by soluble immune complexes are reported to be independent of MPO and the NADPH oxidase.[371,372] Intracellular signals that lead to NETs, depending on the stimulus, include the Ref-MEK-ERK pathway,[373] and protein kinase C isoforms,[374] but also mammalian target of rapamycin–regulated expression of hypoxia-inducible factor 1α is involved in endotoxin-induced NET formation.[375]

Neutrophils from newborns have a reduced capacity to form NETs and a correspondingly reduced capacity to kill bacteria extracellularly.[376] This may relate to a reduction in the content of granule proteins including elastase[376] in neutrophils from newborns.[377]

The view of NETs as an alternative death pathway of neutrophils by which they still serve to defend against microbial invasion[50] is now broadened by observations that demonstrate extrusion of DNA from neutrophils in circulation in a process that requires the participation of platelets to induce NET formation.[378-380] Furthermore, neutrophils may extrude DNA to ensnare bacteria but maintain the capacity to migrate, albeit without the same clear orientation as before becoming anucleate.[381] Formation of NETs are not only to the benefit of the host, because NETs have been shown to promote thrombosis[382-385] and transfusion-related acute lung injury.[386]

Oxygen-Independent Toxicity

Phagocyte granules supply preformed cytotoxic and digestive compounds that play a key role in oxygen-independent killing and digestion of microbes, senescent cells, and particulate debris. In neutrophils, azurophilic (primary) and specific (secondary) granules serve as the main storage reservoir of these compounds. Oxygen-independent pathways complement those dependent on the respiratory burst (see "Oxygen Dependent Toxicity"), and are also important for phagocyte antimicrobial activity under the adverse conditions of hypoxia and acidosis often encountered locally at the site of infection.

Numerous cationic antimicrobial proteins are contained within neutrophil azurophilic granules.[66,360,387,388] Defensins are small (29-25 amino acids) basic peptides that constitute more than 5% of the total cellular protein of human neutrophils, although they are absent in murine neutrophils. These peptides exhibit antimicrobial effects against a broad range of gram-positive and gram-negative organisms, fungi, mycobacteria, and some enveloped viruses. Defensins are also cytotoxic to mammalian cells. Defensins kill target cells by insertion into the cellular membrane and formation of voltage-regulated channels. Defensinlike peptides have also been found in small intestinal Paneth cells and in tracheal epithelium.[387] Bactericidal/permeability-increasing protein (BPI) is a 55-kD cationic protein that has potent cytotoxic effects toward gram-negative bacteria.[389] BPI binds avidly to LPS, leading to both bacterial killing by damaging the cell membrane and to the neutralization of endotoxin associated with the bacterial cell wall and in serum. Serprocidins are a family of 29 kD glycoproteins that are homologous to members of the serine protease superfamily and include azurocidin (CAP37) and four serine proteases (cathepsin G, elastase, proteinase 3, and the recently identified NSP4).[387,390,391] In human neutrophils, serprocidins are even more potent than the defensins in antimicrobial activity and have a broad spectrum of cytotoxicity that is, with few exceptions, unrelated to proteolytic activity. Cathepsin G, elastase, and proteinase 3 are often referred to as neutral proteases because the optimal pH for their proteolytic activity is approximately 7. Azurocidin can bind to endotoxin, which appears to account for its activity for gram-negative bacteria.[392] Azurocidin also is a potent chemoattractant for monocytes as well as fibroblasts and T cells.[392] Exogenous administration of antimicrobial peptides is being studied as an alternative or adjunctive therapy to conventional antibiotics in a number of settings.[387]

Both azurophilic and specific granules contain lysozyme, which hydrolyzes the cell wall of saprophytic gram-positive organisms and may also assist in the nonlytic killing of other organisms.[66] hCAP-18 is a member of the cathelcidin family of antimicrobial peptides, which is cleaved by proteinase-3 after exocytosis. The N-terminal region is homologous to other cathelicidins, whereas the 37-amino acid C-terminal fragment (LL-37) has additional activities, including acting as chemoattractant as well as effects on apoptosis.[61] Specific granules also contain the iron-binding glycoprotein lactoferrin, which has direct bacteriocidal activity both related and unrelated to the chelation of iron compounds required for bacterial metabolism. Lactoferrin may also catalyze the nonenzymatic formation of hydroxyl radicals (OH·)

during the respiratory burst (see “Oxygen-Dependent Toxicity”). Vitamin B_{12} (cobalamin)–binding protein has been proposed to bind the analogous family of compounds found in bacteria to exert an antimicrobial effect.[393] Lipocalin 2, also known as NGAL, interferes with bacterial iron utilization by binding to bacterial ferric-siderophore complexes.[394,395] NGAL-deficient mice demonstrate a major reduction in defense against both *Klebsiella pneumoniae*[396-398] and *Mycobacterium tuberculosis,*[399,400] but NGAL, like most other neutrophil granule proteins, is highly expressed in epithelial cells during inflammation,[61,401,402] and the role of neutrophil-delivered proteins versus epithelial-cell–fabricated proteins has not been determined. Human neutrophil NGAL has, however, been associated with defense against *M. tuberculosis.*[403]

Azurophilic granules contain a variety of hydrolases (see Table 22-2) that have a lower pH optimum (<6), consistent with the lysosomal character of these granules. Studies using indicator dyes and biochemical techniques suggest that after a transient rise, the pH of the phagocytic vacuole falls below 6, which would enhance the activity of these enzymes upon their discharge into the vacuole.[404,405] The acid hydrolases serve primarily a digestive rather than a microbicidal function.[406] Azurophilic granules also contain MPO, which is an important enzyme in microbicidal oxygen-dependent reactions that are described in “Oxygen-Dependent Toxicity.”

Inherited partial or complete deficiency of MPO, which occurs in 0.05% of the population, can occasionally result in increased susceptibility to infection (see “Myelooxidase Deficiency”). Deficiencies in other individual neutrophil granule proteins have not yet been described in humans, but gene-targeted mice lacking the neutrophil granule serine proteases elastase or cathepsin G have impaired host defense against gram-negative sepsis and fungal infections.[407,408] A few rare disorders involving defects in granule formation (SGD) or degranulation (CHS) are associated with recurrent bacterial infections. Inherited mutations in neutrophil elastase are present in patients with cyclic neutropenia (CyN) and severe congenital neutropenia (SCN).[409,410] The mutant forms of elastase may have abnormal properties that exert a toxic effect on granulopoiesis, likely by eliciting an unfolded protein response that induces apoptosis.[411-413]

Oxygen-Dependent Toxicity

The resting neutrophil relies primarily on glycolysis for energy and hence consumes relatively little oxygen.[414] However, within seconds after contacting opsonized microbes or high concentrations of chemoattractants, oxygen consumption increases dramatically, often by more than 100-fold. This “extra respiration of phagocytosis” was first observed in 1933,[415] but it was almost 30 years before it was appreciated that this process was insensitive to mitochondrial poisons and thus not related to increased energy demands.[416] The enzyme complex responsible for this phenomenon, referred to as the NADPH or respiratory burst oxidase, is associated with the plasma and phagolysosomal membranes and catalyzes the transfer of an electron from NADPH to molecular oxygen, thereby forming the superoxide radical (O_2-) (Fig. 22-8).[417-421] Superoxide, although itself a relatively weak microbicidal agent, is the precursor to a family of potent oxidants that are essential for the killing of many microorganisms (see Fig. 22-8).[417,418,422-424] The importance of the respiratory burst to normal host defense is underscored by the recurrent and often life-threatening infections seen in patients with chronic granulomatous disease (CGD), who are genetically deficient in respiratory burst oxidase activity.

The respiratory burst oxidase is a multi-subunit enzyme complex assembled from membrane-bound and soluble

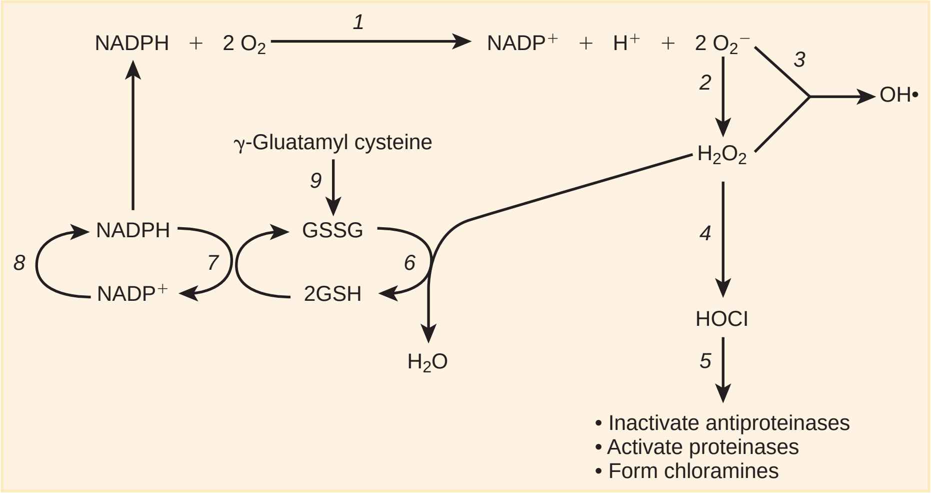

Figure 22-8 Reactions of the respiratory burst pathway. The enzymes responsible for reactions 1 to 9 are as follows: *1,* the respiratory burst oxidase (reduced nicotinamide adenine dinucleotide phosphate *[NADPH]* oxidase); *2,* superoxide dismutase or spontaneous; *3,* nonenzymatic, Fe^{2+} catalyzed; *4,* myeloperoxidase; *5,* spontaneous; *6,* glutathione peroxidase; *7,* glutathione reductase; *8,* glucose-6-phosphate dehydrogenase; *9,* glutathione synthetase. *GSH,* Reduced glutathione; *GSSG,* oxidized glutathione; *NADP,* nicotinamide adenine dinucleotide phosphate. *(Modified from Curnutte J, Orkin S, Dinauer M: Genetic disorders of phagocyte function. In Stamoyannopoulos G, editor:* The molecular basis of blood diseases, *2nd ed. Philadelphia, 1994, WB Saunders, p. 493.)*

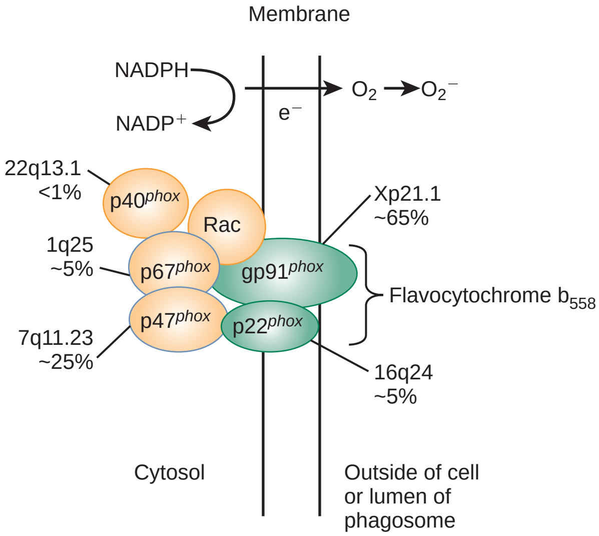

Figure 22-9 Activation of reduced NADPH oxidase. Shown is the assembled form of the enzymatically active NADPH oxidase, along with subunits affected in the four different genetic subgroups of CGD, the approximate incidence, and the chromosomal location of the corresponding gene. Flavocytochrome b_{558}, the redox center of the enzyme, is located in plasma, specific granule, and phagolysosomal membranes. This heterodimer is composed of gp91^{phox} and p22^{phox}, which are affected in X-linked and an AR form of CGD, respectively. Mutations in the genes encoding three soluble regulatory proteins, p47^{phox}, p67^{phox}, and p40^{phox} account for three AR forms of CGD. These subunits are found in the cytosol until phagocyte activation, after which they move as a complex to the membrane to assemble the active NADPH oxidase complex. Membrane translocation of the p47^{phox}-p67^{phox}-p40^{phox} complex is mediated by binding domains on 47^{phox} that are exposed by activation-induced p47^{phox} phosphorylation. Another essential regulatory component of NADPH oxidase is the small GTPase Rac, which in its active GTP-bound state becomes membrane bound and associates with p67^{phox}. By a mechanism that involves an activation domain on p67^{phox}, binding of these multiple regulatory subunits activates the flavocytochrome to catalyze the transfer of electrons from cytosolic NADPH across the membrane via the flavin adenine dinucleotide and heme redox centers to molecular oxygen, thereby forming superoxide in the extracellular or intraphagosomal compartment. No cases of CGD have been reported to result from mutations in Rac. *CGD,* Chronic granulomatous disease; *NADP,* nicotinamide adenine dinucleotide phosphate; *NADPH,* reduced nicotinamide adenine dinucleotide phosphate; O_2, oxygen; O_2^-, superoxide; *phox,* phagocyte oxidase. *(Modified from Dinauer MC:* Chronic granulomatous disease and other disorders of phagocyte function, *Washington, DC, 2005, American Society of Hematology, p. 83–89.)*

proteins upon phagocyte activation (Fig. 22-9). Five polypeptides, gp91^{phox}, p22^{phox}, p47^{phox}, p67^{phox}, and p40^{phox}, that are essential for normal respiratory burst function have been identified (Table 22-7), and mutations in the corresponding genes are responsible for five different genetic subgroups of CGD. The oxidase subunits have been given the designation *phox*, for *ph*agocyte *ox*idase. Neutrophils have the highest expression level of the NADPH oxidase, followed by monocytes, macrophages, eosinophils, and dendritic cells. B lymphocytes also express the NAPDH oxidase, but at very low levels, and even smaller amounts are reported in T lymphocytes.

An unusual b-type flavocytochrome, located in the membrane of secretory vesicles, gelatinase granules, and specific granules, mediates electron transfer in the oxidase complex. It is often referred to as *flavocytochrome* b_{558}, for its spectral peak of light absorbance at 558 nm, or as *flavocytochrome* b_{245} in reference to its midpoint potential of −245 mV, which is extremely low.[425] This flavocytochrome is a heterodimer that contains a 91-kD glycosylated protein, gp91^{phox}, and a nonglycosylated subunit, p22^{phox}.[426-429] The gene for gp91^{phox}, which is the site of mutations in the X-linked form of CGD, was one of the first human disease–associated genes to be identified by positional cloning.[429] gp91^{phox} is the redox center of the oxidase and contains both flavoprotein and heme-binding domains in its cytosolic and membrane-spanning portions, respectively.[419,420] This subunit is also sometimes called *NADPH oxidase (NOX) 2,* referring to its number in a series of homologous flavocytochromes.[430,431] The p22^{phox} subunit is also an integral membrane protein and provides an important docking site for p47^{phox} during NADPH oxidase assembly. Heterodimer formation with gp91^{phox} is essential for heme incorporation and intracellular stability of both flavocytochrome subunits.[432,433]

The p47^{phox}, p67^{phox}, and p40^{phox} subunits are found in the cytosol as a complex that is stabilized by intermolecular interactions that include those mediated by SH3 domains and proline-rich SH3 binding motifs within these proteins.[419,420] Phagocyte activation induces translocation of this complex to the flavocytochrome, which is triggered by the phosphorylation of p47^{phox} to expose additional SH3 domains that bind to a proline-rich target SH3-binding sequence in p22^{phox}.[420,421] The p47^{phox} subunit is necessary for translocation of p67^{phox} to the membrane of activated neutrophils based on studies of p47^{phox}-deficient CGD neutrophils.[419,434] However, substantial amounts of superoxide can be generated from neutrophil membranes in vitro in the absence of p47^{phox}, provided that high concentrations of p67^{phox} and Rac-GTP are supplied.[419] Hence, p47^{phox} acts as an "adaptor" protein to mediate translocation of p67^{phox} and to position it correctly in the active NADPH oxidase complex. The p40^{phox} plays a specialized role in stimulating high levels of superoxide production on phagosome membranes via a domain that binds to the membrane lipid phosphatidylinositol 3-phosphate.[435-439] p40^{phox} may also help with stabilization of p67^{phox} on flavocytochrome b–containing granule membranes as they are recruited to the phagosomes.[440]

The active NADPH oxidase also requires the GTP-bound form of the Rho GTPase, Rac.[82,314,419,420] The main target of Rac-GTP is the p67^{phox} subunit, which contains a Rac-binding domain created by four α-helical tetratricopeptide repeat motifs.[441] The GTP-bound form of Rac also appears to interact with flavocytochrome *b*.[442]

Oxidase assembly is triggered by receptor-mediated binding of many soluble chemoattractants (see Table 22-4), which requires higher concentrations of these molecules compared with the initiation of chemotaxis. The binding of opsonized microbes to Fcγ and complement receptors or of fungi to β-glucan receptors are other major physiologic triggers of the respiratory burst, which is activated at sites of contact.[443,444] Two critical events downstream of receptor binding are the phosphorylation of p47^{phox} and the activation of Rac to its GTP-bound state.[314,419,420] The functional oxidase complex is assembled at the plasma membrane in response to

soluble agonists. During phagocytosis, additional flavocytochrome *b* for NADPH oxidase assembly is delivered to the phagosome by the membrane fusion of specific granules, which contain the majority of the neutrophil's supply of flavocytochrome *b*.[49,66,360,445] Since release of O_2^- occurs largely at the extracellular side of the membrane, oxidants are released at sites of microbial contact or within the phagocytic vacuole, where they can interact with granule contents to potentiate their microbicidal effects.

Based on the redox properties of the flavocytochrome b_{558}, the following pathway has been proposed for transfer of electrons from NADPH to oxygen (O_2) in the respiratory burst (see reaction 1 in Fig. 22-8):

NADPH	flavin	heme	O_2	O_2^-
→	→	→	→	
–330 mV	–256 mV	–245 mV	–160 mV	

The flavocytochrome spans membrane, so that NADPH is oxidized at the cytoplasmic surface and oxygen is reduced to form O_2^- on the outer surface of the plasma membrane (or inner surface of the phagosomal membrane).[417]

Once formed, the O_2^- radical is first converted, either spontaneously or by means of superoxide dismutase, into hydrogen peroxide (H_2O_2; see reaction 2 in Fig. 22-8). Azurophilic granule (derived MPO) in the presence of halides catalyzes the conversion of H_2O_2 to hypochlorous acid (HOCl), the active agent in household bleach (see reaction 4 in Fig. 22-8). H_2O_2 may also be converted into OH· in a nonenzymatic reaction with O_2^- catalyzed by either iron or copper ions (see reaction 3 in Fig. 22-8). H_2O_2, HOCl, and OH· are all strong oxidants that participate in microbial killing within the phagocytic vacuole.[423,424,446] Reactive oxidants also regulate phagocyte proteolytic activity by activating latent phagocyte metalloproteinases (such as collagenase and gelatinase) and inactivating plasma antiproteinases.[68,305] Enhanced phagocyte proteolysis at localized sites may be important for facilitating cellular migration into inflamed tissues, destruction of microbes, and removal of cellular debris.

Other enzymatic pathways related to oxidant generation include the detoxification of H_2O_2 by glutathione peroxidase and reductase (see reactions 6 and 7, Fig. 22-8).[423,424,446] Glutathione is produced from γ-glutamyl cysteine by the enzyme glutathione synthetase (see reaction 9, Fig. 22-8). Other important antioxidant systems in phagocytes and other tissues include catalase, which catalyzes the conversion of H_2O_2 into O_2 and water; ascorbic acid; and α tocopherol (Vitamin E).[447] The generation of NADPH is important in providing a source of reducing equivalents for the glutathione detoxification pathway as well as the respiratory burst itself. NADPH is replenished from $NADP^+$ by leukocyte glucose-6-phosphate dehydrogenase (G6PD; see reaction 8, Fig. 22-8) in the hexose monophosphate shunt.

A second oxygen-dependent pathway with antimicrobial effects involves the generation of NO from the oxidation of L-arginine to L-citrulline. This reaction is catalyzed by NO synthase (NOS), with molecular oxygen supplying the oxygen in NO.[448-450] There are three different NOSs, two of which are constitutively expressed in a variety of tissues, including endothelium, brain, and neutrophils.

Expression of a third, high-output isoform of NOS (inducible NOS [iNOS]) is inducible by inflammatory stimuli in a variety of cells, including macrophages and neutrophils, where it has a wide spectrum of antitumor and antimicrobial activity against bacteria, parasites, helminths, viruses, and tumor cells.[448-450] NO can also interact with superoxide to form peroxynitrite, which mediates tyrosine nitration of cellular and bacterial proteins.[422] High levels of iNOS-catalyzed NO production are readily elicited in normal mouse macrophages by exposure, for example, to IFN-γ and endotoxin. In human monocytes and macrophages, IFN-α/β, IL-4 plus anti-CD23, or chemokines can induce iNOS expression.[449] The expression of iNOS has been detected in a variety of inflammatory and infectious diseases in humans, including malaria, hepatitis C, tuberculosis, tuberculoid leprosy, and acquired immunodeficiency syndrome dementia.[449] Cytokine-activated human neutrophils also exhibit inducible production of NO that leads to nitration of ingested bacteria.[451]

Specialized Functions of Mononuclear Phagocytes

Mononuclear phagocytes, particularly tissue macrophages, participate in a broad range of activities important for tissue homeostasis and repair as well as in the host defense against viruses, bacteria, fungi, and protozoa (Box 22-1).[182-184,188,452,453] From the standpoint of antimicrobial function, activated macrophages play a key role in the ingestion and killing of intracellular parasites, such as mycobacteria, *Listeria, Leishmania, Toxoplasma,* and some fungi,[183,454] although some intracellular organisms have evolved specialized evasion mechanisms.[455] Both oxygen-dependent and oxygen-independent systems are involved in this process, as described. When microbes (most characteristically mycobacteria, but any other organism or particle) cannot be fully ingested or killed, macrophages fuse in a cytokine-mediated process to form giant cells and granulomas.[456,457]

  - Débridement and phagocytosis
  - Secretion of growth factors for endothelial cells and fibroblasts
- Hematopoiesis
  - Secretion of growth factors
- Iron metabolism
- Lipid metabolism

IFN-γ, one of the principal macrophage-activating factors, is secreted by T lymphocytes as well as by macrophages and neutrophils.[102,183,184,232,458] The cytokine induces changes in macrophage gene expression through the JAK–signal transducer and activator of transcription (STAT) pathway, elements of which are shared by many other cytokines, including IL-2, IL-6, and G-CSF.[102,104] Endotoxin, the bacterial LPS derived from gram-negative bacteria, is another important trigger of macrophage activation through pathways involving CD14 and TLRs.[183,184]

The classically activated, or M1 macrophages, are induced and supported by IFN-γ or IFN-β in combination with TNF-α. NK cells or other IFN-γ-producing lymphocytes can initiate this activation, and it may be sustained by an autocrine loop where INF-β and TNF-α are induced by danger signals sensed through TLRs expressed on the macrophage.[183,184] M1 macrophages are indispensable for killing of intracellular pathogens and are also producers of proinflammatory cytokines such as TNF-α, IL-1, IL-6, Il-12, and IL-23. These are also potent activators of T-helper cells (Th1 and Th17).[159,183,184] Macrophages may also develop into the alternatively activated or M2 phenotype that have antiinflammatory functions and promote tissue healing.[459] IL-4 and IL-13 are key inducers of M2 macrophages.[460,461] These cytokines are primarily produced by eosinophil and basophils and CD4+ type 2 helper T cells (Th2 cells); also IL-10, IL-21, and GM-CSF support the M2 phenotype. The M2 macrophages secrete antiinflammatory cytokines, primarily IL-10 and TGF-β. These macrophages are important for resolution of inflammation.[159,183,184,459]

A particular activity of macrophages is the inhibition of antitumor activity of T cells. This is ascribed to myeloid-derived suppressor cells (MDSCs) that share many functional activities with M2 macrophages.[159,462] Neutrophil subsets have also been described that function as inhibitors of T-cell function.[463-466] A common feature of these MDSCs is the ability to deplete T cells of arginase.[467] The development of MDSCs is supported by local factors secreted by tumors, such as TGF-β and GM-CSF. Because many tumors induce a systemic inflammatory response, at least neutrophil MDSCs may represent immature neutrophils liberated from the bone marrow. LPS induces liberation of such immature neutrophils with features characteristic of MDSCs in blood.[66,468]

Interactions of macrophages with T and B cells are essential for the development of cellular and humoral immunity.[78,204,469,470] Macrophage production of IL-1, and subsequent interactions between stimulated T and B cells, leads to B cell production of antigen-specific immunoglobulins. Macrophages are also major physiological sources of cytokines and chemokines that regulate both the innate and adaptive immune systems.[80,182,204,469] As a source of “endogenous pyrogens,” they are responsible for the production of fever in response to infection or inflammation.[471]

Macrophages participate in many aspects of wound repair.[472,473] The early phases of this process are dominated by an influx of neutrophils, followed by the migration of monocytes that differentiate into activated

Box 22-2 **Products Secreted by Mononuclear Phagocytes**

ENZYMES

- Acid ceramidase, lipase, phosphatase, deoxyribonuclease (DNase), ribonuclease (RNase)
- α-Iduronidase, α-L-fucosidase, α-mannosidase, α-neuraminidase
- α-Naphthylesterase
- Angiotensin-converting enzyme
- Arginase
- Aspartylglycosaminidase
- β-Glucuronidase, β-glucosidase, β-galactosidase
- Cathepsins, collagenase, elastase
- Leucine-2-naphthylaminidase
- Lipoprotein lipase
- Lysozyme
- *N*-acetyl-β-galactosaminidase, *N*-acetyl-β-glucosaminidase
- Phospholipase A_2
- Sphingomyelinase
- Sulfatases

OXIDANTS

- Hydroxyl radical, hydrogen peroxide, hypohalous acids, nitric oxide, peroxynitrate, superoxide anion

BINDING PROTEINS

- Avidin, apolipoprotein E, acidic isoferritins, gelsolin, haptoglobin, transcobalamin II, transferrin

COAGULATION SYSTEM PROTEINS

- Factors V, VII, IX, X, XIII
- Tissue factor/procoagulant activity (PCA), plasminogen activator, urokinase, thrombospondin, plasminogen activator inhibitors, plasmin inhibitors

LIPID METABOLITES

- Prostaglandins E_2, F_2, I; thromboxane A_2; leukotrienes B, C, D, E; malonyldialdehyde; mono-dihydroxyeicosatetraenoic acids; platelet-activating factor

COMPLEMENT SYSTEM PROTEINS

- C1, 2, 3, 4, 5; factors B, D, H; properidin; C3b inactivator

CYTOKINES AND GROWTH FACTORS

- Interferons (INFs) α, β, γ
- Interleukin (IL) 1α, 1β, 6, 8
- Tumor necrosis factor (TNF) α
- Fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), transforming growth factor β (TGF-β)
- Colony-stimulating factors (CSFs) granulocyte (G), granulocyte/monocyte (GM), monocyte (M)
- Macrophage inflammatory proteins (MIPs) 1α, 1β, 2
- Monocyte chemoattractant proteins (MCPs) 1, 2, 3
- Thymosin B_4

MATRIX PROTEINS

- Fibronectin, proteoglycans, thrombospondin

OTHER METABOLITES, PEPTIDES, AND PROTEINS

- Glutathione, purines, pyrimidines
- Sterol hormones, including 1α-25-dihydroxyvitamin D_3

macrophages, and finally, the appearance of T lymphocytes. Proliferating fibroblasts secrete collage and other matrix proteins important for wound closure and tissue remodeling, and migrating keratinocytes regenerate the epithelial surface. Both neutrophils and macrophages protect against infection and dispose of phagocytosed debris. Mononuclear phagocytes also elaborate fibroblast, epithelial, and angiogenic growth factors (Box 22-2), which stimulate the normal progression of tissue repair and neovascularization that characterize the later phases of wound healing.[185,472,473]

Macrophages ingest and dispose of apoptotic and necrotic cells.[224,452,474-476] This function not only contributes to cellular processing for antigen presentation but also plays a critical role in tissue remodeling and homeostasis, embryological development, and the resolution of inflammation.[9] A redundant and promiscuous system of receptors including integrins, scavenger receptors, complement receptors, calreticulin, CD14, and Mer receptor recognize and effect the uptake of apoptotic cells. Resident tissue macrophages, particularly those lining the sinusoids of the spleen and liver (formerly known as the *reticuloendothelial system*), clear senescent and antibody-bound blood cells from the circulation.[187,477,478]

Iron from the catabolism of hemoglobin in aged erythrocytes is incorporated into ferritin and hemosiderin, where it accounts for about two-thirds of the body's store of reserve iron. Iron in this macrophage storage pool turns over and returns in a transferrin-bound form to the bone marrow for new red blood cell synthesis (see Chapter 11).[479] Sequestration of iron in macrophages leads to the anemia of chronic disease.[480] This is largely regulated by hepcidin, a small peptide synthesized by the liver in response to Il-6, which binds to and induces degradation of ferroportin, the mediator of iron export from macrophages and enterocytes.[481-485]

Monocytes and macrophages contribute to the pathophysiology of atherosclerosis through the uptake, metabolism, and oxidation of LDL and very low density lipoprotein by receptor-mediated endocytosis.[486,487] Macrophages in blood vessel walls that are exposed to sufficient quantities of cholesterol develop into foam cells characteristic of atherosclerotic plaques[488] and contribute to the important inflammatory component of plaque formation and destabilization.[489]

Specialized Functions of Eosinophils and Basophils

Eosinophils and basophils, which share many of the functional characteristics of neutrophils and mononuclear phagocytes, participate in distinctive aspects of the inflammatory response and interact with each other in the context of certain allergic reactions.[119,122,123] Eosinophils and mast cells are often situated beneath epithelial surfaces exposed to environmental antigens, such as the respiratory and GI tracts, where they may be actively involved in mucosal immune responses. However, the role of eosinophils, basophils, and mast cells are better known in pathologic settings than in normal homeostasis.

Eosinophils appear to have both immunoenhancing and immunosuppressive functions (Table 22-8).[14,117,119,122,123] Although capable of ingesting and killing bacteria, eosinophils are not particularly efficient at this task. Rather, they possess an unusual ability to destroy invasive metazoan parasites, especially helminthic parasites. Eosinophils bind to the surface of both adult and larval helminths and inflict damage through release of cationic granule proteins and by the generation of reactive oxidants, including the eosinophil peroxidase–catalyzed formation of hypohalous acids via the action of the respiratory burst and eosinophil peroxidase.[14,117]

Eosinophil production of the lipid inflammatory mediators, leukotriene C4 and PAF, play a role in the pathogenesis of allergic diseases.[14] PAF and leukotriene C_4 can induce smooth muscle contraction and promote the

TABLE 22-8 Eosinophil Function

Function	Mechanism
Defense against helminths (both larval and adult forms)	Binding of eosinophils to surface Peroxidation of larval surface mediated by eosinophil peroxidase Toxicity to larval surface by released major basic protein (MBP)
Immunosuppression of immediate hypersensitivity reactions	Engulfment of most cell granules Release of prostaglandin E_1/E_2 to suppress basophil degranulation Release of histaminase Oxidation of slow-reacting substance of anaphylaxis Release of phospholipase D to inactive mast cell platelet-activating factor Release of MBP for binding of mast cell heparin Release of plasminogen to reduce local thrombus formation

secretion of mucous, and PAF itself is a potent activator of eosinophils. The release of eosinophil granule contents may also contribute to localized tissue damage. Purified eosinophil MBP, for example, can cause cytopathic changes in tracheal epithelium in vitro that are similar to the changes observed in asthmatic patients.

Eosinophils may also perform an immunosuppressive function in immediate hypersensitivity reactions (see Table 22-8). IgE-activated basophils or mast cells release eosinophilic chemotactic factor of anaphylaxis, which recruit eosinophils to the site. Subsequent eosinophil degranulation releases products that can inactivate inflammatory mediators. For example, histaminase inactivates histamine, phospholipase B inactivates PAF, MBP inactivates mast cell heparin, and lysophospholipase prevents the generation of arachidonic acid metabolites.[490]

Basophils and mast cells are central participants in a variety of inflammatory and immunologic disorders, particularly immediate hypersensitivity diseases, and they may also play a role in host defense against bacterial infections.[122,491,492] Basophils and mast cells express plasma membrane receptors that specifically bind with high affinity the Fc portion of the IgE antibody (Fcε receptors).[346] After active or passive sensitization with IgE, exposure to specific multivalent antigen triggers an almost immediate release of granule contents (anaphylactic degranulation) and the synthesis and release of newly generated chemical mediators such as leukotriene C_4, which stimulates smooth muscle contraction, mucous secretion, and vasoactive changes. Degranulation can also be triggered in response to insect venoms, radiocontrast dye, and other irritants. Studies conducted in 1994 on mutant mice engineered by gene targeting to lack Fcγ and/or Fcε receptors have shown that mast cell FcγRIII receptors are essential in activating the inflammatory response to IgG immune complexes (Arthus reaction), heretofore an unrecognized role for the mast cell.[493] Mast cells can secrete numerous mitogenic or inflammatory cytokines, including many ILs (1, 3, 4, 5, and 6), chemokines, GM-CSF, and TNF-α, that are also likely to regulate leukocyte recruitment and inflammation in IgE-dependent reactions and immune complex injury.[158,159] Inflammatory cytokines and leukotrienes released from tissue mast cells have been recognized to play an important role in neutrophil recruitment during the acute response to bacterial infection.[494-497]

Pathologic Consequences of Phagocyte Activation and Inflammatory Response

Although it normally serves a protective function, the inflammatory response can also result in damage to host tissues. The release of proteases, oxygen radicals, and proinflammatory cytokines by activated phagocytes appears to play a major role in the generation of tissue injury in a wide variety of pathologic inflammatory processes (Box 22-3).[222,266,305,498-500] For example, neutrophil elastase has been implicated in the pathogenesis of emphysema in both adult smokers and individuals with α1-antitrypsin deficiency. Neutrophil granule proteases may contribute to the joint destruction in rheumatoid arthritis and other chronic arthropathies. Neutrophils are also believed to play a key role in the systemic inflammatory response syndrome, a term that has been created to encompass the host response to both infectious (e.g. gram-negative sepsis) and noninfectious (e.g. pancreatitis, trauma) etiologies, and can lead to organ dysfunction and tissue damage.[500] Sequestration of activated neutrophils in the pulmonary capillary bed and subsequent release of tissue-damaging agents is an important component in the development of adult respiratory distress syndrome. Activation of the complement cascade by artificial membrane surfaces during hemodialysis and cardiopulmonary bypass also can result in neutrophil activation, intrapulmonary sequestration, and lung injury. Macrophages are integral to the pathophysiology of atherosclerosis by uptake of serum lipoproteins and contribute an important inflammatory component that influences atherosclerotic plaque development and rupture.[489,501] In addition to their cytotoxic effects, oxidative products released by activated phagocytes are also mutagenic, as documented by plasmid mutagenesis, sister chromatid exchange, and transformation of cells in culture.[502,503] Hence the increased risk of malignancy observed with certain chronic inflammatory states, such as ulcerative colitis or chronic hepatitis, has been postulated to be in part related to oxidant-induced carcinogenesis.

The development of antiinflammatory interventions based on agents that block leukocyte adhesion or inhibit the action of specific proinflammatory agents has been an area of intense interest. IL-1 receptor antagonists are used to treat autoinflammatory diseases such as familial Mediterranean fever as well as rheumatoid arthritis and are being evaluated in a broad range of inflammation-associated states.[231] TNF-α antagonists are now widely used for treatment of inflammatory bowel disease, rheumatoid arthritis, and other autoimmune disorders.[231,504] Antagonists of leukocyte integrins have shown benefit in phase II and III studies for inflammatory bowel disease, psoriasis, and multiple sclerosis.[263] However, although protective effects of monoclonal antibodies directed against β_2 integrins, ICAM-1, or selectins were found in various animal models of inflammation including ischemia-reperfusion injury, endotoxic shock, and acute arthritis, results from clinical trials failed to show significant benefit.[263] The contributions of nonphagocytic cells to inflammatory tissue injury must also be kept in mind. For example, the adult respiratory distress syndrome can occur in the presence of severe neutropenia.[505] Moreover, despite the adverse consequences of the acute inflammatory process, these events are also important for normal healing. For example, the use of antiinflammatory agents in myocardial infarction, which can decrease infarct size acutely, results in impaired healing of the myocardium and the formation of fragile scar tissue.[498] Finally, the impact of the new antiinflammatory biologic agents on host defense must be kept in mind, particularly if such agents are being used in combination with other immunosuppressive drugs such as steroids. For example, patients receiving TNF-α antagonists have increased rates of tuberculosis and infections with endemic mycosis or intracellular bacterial pathogens.[506]

QUANTITATIVE GRANULOCYTE AND MONONUCLEAR PHAGOCYTE DISORDERS

This section reviews clinical disorders associated with disturbances in granulocyte number, with particular emphasis on syndromes in which the granulocyte abnormality is a central feature. Several disorders have now been associated with specific genetic defects, although the molecular pathophysiology leading from the gene to the phenotype often remains obscure. This section of the chapter is organized by clinical characteristics of the disorders, with genetic and functional laboratory data provided where available.

Neutropenia

Definition and Classification

Neutropenia is defined as a decrease in the absolute number of circulating neutrophils in the blood. Normal neutrophil levels should be stratified for age, race, and other factors. For whites, the lower limit for normal absolute neutrophil count (ANC; total neutrophils and bands) is 1000 cells per µL in infants between 2 weeks and 1 year of age; then it rises after infancy to 1500 cells per µL. Persons of African descent have somewhat lower neutrophil counts, with ANC less than 1500 cells per µL in 4.5% of African-American participants in one U.S. survey.[507] This is entirely attributable to the lower ANC in the subpopulation with the Duffy negative (Fy–/–) blood group.[508] This blood group, selectively enriched in populations in the malarial belt of Africa, is associated with ANCs 200 to 600 cells per µL less than those who are Duffy positive. Falsely low white blood cell counts can result when counts are done long after blood is drawn or after leukocyte clumping in small clots or in the presence of certain paraproteins.

Neutropenia can represent disturbances in neutrophil production, altered distribution of neutrophils between the circulating and the marginated or tissue pools (pseudoneutropenia), increased peripheral utilization or destruction, or combinations of these causes. However, assays of leukokinetics and myelopoiesis are not routinely available, so mechanisms may be hard to identify. Classifications based on biochemical or functional studies are also difficult because of the paucity of neutrophils in the circulation of neutropenic patients. In general, neutropenic syndromes are broadly classified as intrinsic because of defects in myelopoiesis or as acquired, as a result of extrinsic factors such as drugs, infections, or autoantibodies (Box 22-4). Congenital neutropenias are now classified largely on the basis of known genetic defects.

The clinical significance of neutropenia depends upon the level of depression of the ANC. Mild neutropenia with neutrophil counts of 1000 to 1500 cells per µL and moderate neutropenia with counts of 500 to 1000 cells per µL are generally not clinically significant with respect to host defense, but these situations may warrant evaluation to determine the underlying cause. Severe neutropenia refers to an ANC below 500 cells per µL, with the term *agranulocytosis* usually reserved for counts

*Types of neutropenia are listed in order of discussion in the text.

below 200 cells per μL. Children with severe chronic neutropenia can be registered with the Severe Chronic Neutropenia International Registry (SCNIR; http://depts.washington.edu/registry/).

Symptoms of Neutropenia

The hallmark of neutropenia is an increased susceptibility to bacterial and fungal infection; neutropenia by itself does not diminish host defense to viral or parasitic infections. The most common types of pyogenic infections in patients with significant neutropenia are cellulitis, furunculosis, superficial or deep cutaneous abscesses, pneumonia, and septicemia.[509-512] Stomatitis, gingivitis, and periodontitis may be presenting signs of neutropenia that develop into chronic problems. Perirectal inflammation and otitis media (especially in younger children) occur as well. Endogenous bacteria are the most common cause of infections, but colonization or infection may occur with a variety of nosocomial and opportunistic organisms. The most commonly isolated organisms from neutropenic patients are *Staphylococcus aureus* and gram-negative bacteria, but almost any organism can appear, particularly in hospitalized patients or those with frequent or prolonged courses of antibiotics. The usual symptoms and signs of local infection—such as exudates, fluctuation, ulceration, and regional adenopathy—may be less evident in patients with neutropenia than in normal individuals.[513]

Susceptibility to bacterial infection, even with severe neutropenia, can be quite variable, depending on the underlying etiology. For example, some patients with chronic neutropenia resulting from autoantibodies do not experience serious infections over a period of many years even with neutrophil counts as low as 200 cells per μL, most likely because these individuals have rapid production and transit of normal neutrophils with relative preservation of neutrophil delivery to tissues.[514] Many patients with chronic neutropenia also have normal to increased numbers of circulating monocytes, an alternative phagocyte.[515] However, the recruitment of monocytes to inflammatory sites is delayed relative to neutrophils, and monocytes are not as efficient as neutrophils in ingesting bacteria.[516,517] Thus monocytes appear to provide only marginal protection against pyogenic organisms in patients with severe neutropenia. It is likely that the humoral, cell-mediated, and tissue macrophage immune systems also play important alternative or compensatory roles preventing infection in these individuals.

Neutropenia Caused by Intrinsic Defects in Granulocytes or Their Progenitors

These disorders are also discussed in Chapter 8.

Reticular Dysgenesis. The selective failure of stem cells committed to myeloid and lymphoid development leads to reticular dysgenesis, one of the rarest and most severe forms of severe combined immunodeficiency.[518-521] It is characterized by severe leucopenia—including both agranulocytosis and lymphopenia; defective cellular and humoral immunity functions; and absence of lymph nodes, tonsils, Peyer's patches, and splenic follicles—as well as sensorineural hearing loss. Erythroid and megakaryocyte development is normal. All reported infants have died of bacterial or viral infections within the first weeks of life, except a few treated with hematopoietic stem cell transplantation (HSCT).[522-524] The underlying genetic defects in this AR disorder are biallelic mutations in the *AK2* gene, encoding the mitochondrial energy metabolism enzyme adenylate kinase 2.[525,526] As discussed below, other mitochondrial enzyme deficiencies have been associated with isolated neutropenia.

Severe Congenital Neutropenia. SCN was first described by Kostmann in 1956 as an AR disorder associated with severe neutropenia that was identified in the population of an isolated northern parish of Sweden.[527] Other forms of SCN have since been identified with de novo occurrence and AD, AR, or X-linked inheritance.[528-531] *SCN* (Online Mendelian Inheritance in Man [OMIM] # 202700) refers to the entire disorder regardless of inheritance or genotype, whereas Kostmann disease (OMIM # 610738) refers to the AR subtype caused by mutations in the *HAX1* gene[532] (see later in this section). This disorder is also discussed in Chapter 8.

The incidence of SCN is approximately two cases per million population.[533] Affected patients generally maintain ANCs below 200 cells per μL, which has been documented on the first day of life in several cases.[534] Episodes of fever, skin infections (including omphalitis), stomatitis, pneumonia, and perirectal abscesses typically appear during the first months of life. Infections often disseminate to the blood, meninges, and peritoneum, and are usually caused by *S. aureus*, *Escherichia coli,* and *Pseudomonas* species. Before the current era of G-CSF therapy, most patients died in the first 1 to 2 years of life,[530,535] and survivors were known to be at risk for developing myelodysplastic syndrome (MDS) and acute myelogenous leukemia (AML).[535-537]

Peripheral blood counts generally show, in addition to agranulocytosis, moderate to marked monocytosis, mild to moderate eosinophilia, and secondary changes such as anemia and thrombocytosis. G-CSF production in patients with SCN appears to be normal, if not elevated.[538,539] Antineutrophil antibodies may be present, and a positive test should not be used to rule out SCN.[540]

Bone marrow examination characteristically shows a myeloid "maturation arrest" at the myelocyte stage of development, with normal to increased numbers of promyelocytes but few if any more mature forms.[528,533] The promyelocytes may show dysplastic morphology, including large size, atypical nuclei, and vacuolated cytoplasm. Marrow eosinophilia and monocytosis is common and does not change during treatment. Cellularity is usually normal or slightly decreased. Megakaryocytes are normal in number and morphology.

The genetic basis of 40% to 80% of SCN cases derives from mutations in the *ELANE* gene (formerly termed *ELA2*),[409,541,542,543] which encodes neutrophil elastase and is also responsible for the related but distinct disorder, CyN (discussed later in this section). *ELANE*-related SCN may arise sporadically by de novo mutation or appear in kindreds with an AD Mendelian inheritance pattern, most

Figure 22-10 Linear representation of the *ELANE* gene showing the locations and types of mutations observed in 188 patients with SCN *(upper panel)* and 119 patients with CyN *(lower panel)* from the Severe Chronic Neutropenia International Registry. *Red boxes* indicate mutations associated with myelodysplastic syndrome and acute myelogenous leukemia *(MDS/AML)*, *red numbers* within the boxes indicate the numbers of affected patients if there are more than one, and *red numbers* in the summary boxes in the left margin indicate total numbers of patients with MDS/AML. Human Genome Variation Society nomenclature was used to describe the mutations. *(Data from Makaryan V, Zeidler C, Bolyard AA, et al: The severe chronic neutropenia international registry and repository, clinical outcomes for patients with severe chronic neutropenia due to mutations in the gene for neutrophil elastase.* Elane *[ASH Annual Meeting Abstracts] 120:3275, 2012.)*

dramatically illustrated by the six affected children from five families, all conceived by sperm from the same anonymous donor.[529,544]

The SCNIR analyzed 188 patients with SCN who had 94 mutations and 119 patients with CyN who had 22 mutations (see Fig. 22-10).[545] Most *ELANE* mutations resulted in only an SCN or the cyclic phenotype (Fig. 22-10), but 12 mutations were observed in both patients with CyN and SCN. A number of recurring mutations were observed only in CyN, including Q97L, D174ins, and W241G and conversely, a number of recurring mutations were observed only in SCN, including A57T, R103P, and G214R.

How mutations in neutrophil elastase result in the cyclical production of neutrophils and other blood cells is not entirely understood. Bone marrow samples from both patients with CyN and patients with SCN demonstrate increased apoptosis of neutrophil precursors.[546-549] Thus expression of mutant neutrophil elastase appears to induce excessive apoptosis, most likely through either aberrant subcellular targeting of the protein[548] or induction of a strong unfolded protein response.[411,412,550]

Additional very rare cases of AD SCN appear to arise from mutations in the *Gfi1* gene,[551] which encodes a transcriptional repressor that inhibits multiple genes involved in neutrophil maturation, including *ELANE*.[17,18] Resultant overexpression of *ELANE* could lead to apoptosis by either of the mechanisms discussed previously.

AR SCN can be caused by defects in several genes, including *HAX1*, an antiapoptotic gene that is responsible for the classic Kostmann syndrome,[532] and *G6PC3*. *HAX1* encodes a multifunctional protein that is involved in the regulation of apoptosis, as well as cell motility, signal transduction, and mRNA processing.[552-554] Other genes associated with AR SCN include *VPS45*, which encodes an endosomal trafficking regulator,[555,556] and *G6PC3*, which encodes a neutrophil-specific catalytic subunit of glucose-6-phosphatase and may thus be considered functionally similar to glycogen storage disease type 1b (see later discussion in this section) but with pathology limited to the neutrophil.[557] In contrast to *ELANE*, which is expressed only in myeloid cells, these genes are broadly expressed in many tissues and organs. As a result, some patients with *HAX1* protein defects have associated neurological deficits; *G6PC3* defects were originally described in a cohort of patients with cardiac anomalies, urogenital abnormalities, and venous angiectasias[558]; and *VPS45* mutations are associated with neutrophil dysfunction, bone marrow fibrosis, and nephromegaly. However, both *HAX1* and *G6PC3* mutations can also be responsible for isolated neutropenia without an extended phenotype.[559,560] *G6PC3* has also been associated with rare cases of atypical CyN,[561] indicating that, as for *ELANE*, the same mutation can produce either the severe or CyN phenotype depending upon the genetic background.

Other rare mutations responsible for an SCN phenotype include gain-of-function mutations in the X-linked Wiskott-Aldrich syndrome (WAS) gene[562,563] and constitutional defects (as opposed to acquired mutations; see later) in the gene encoding the G-CSF receptor.[564,565] Overall, approximately 60% of patients with a diagnosis of SCN can now be given a precise genetic diagnosis.

G-CSF, the standard treatment modality for SCN, has greatly improved both life span and quality of life for these patients.[566-570] Until the availability of this cytokine in the 1980s, severe neutropenia would inevitably lead to fatal infections in the majority of patients, despite supportive care with prophylactic trimethoprim-sulfamethoxazole, aggressive use of antibiotics at the time of documented infections, and scrupulous attention to oral hygiene. More than 95% of patients with SCN respond to G-CSF treatment with an increase in the ANC to greater than 1000 per µL, with documented reduction in infections.[530,566,571,572] There is often a delay of 7 to 10 days before the rise of peripheral blood neutrophil counts at the start of treatment. In patients enrolled in the SCNIR between 1993 and 1999, more than 90% of patients with congenital neutropenia responded to G-CSF treatment with rises in ANC to more than 1×10^9/l and required significantly less antibiotic therapy and fewer hospitalizations.[531] SCN patients required G-CSF doses ranging from 0.01 to 242 µg/kg/day (mean 12.6 µg/kg/day and standard deviation [SD] 19.3 µg/kg/day).[567] These doses are significantly higher than those needed for cyclic or idiopathic neutropenia.[530,567] The percentage of maturing neutrophils in the bone marrow increases with G-CSF, although morphologically abnormal promyelocytes with vacuolized and asynchronous nuclear-cytoplasmic maturation can persist, and the number of monocytes and eosinophils in the bone marrow and peripheral blood may remain high.[533]

Based on data from the SCNIR, a starting daily dose of G-CSF at 5 µg/kg/day is recommended, increasing gradually if necessary to as high as 100 µg/kg/day for at least 14 days at each dose to achieve a neutrophil count of 1000 to 2000 per µL.[572-574] The drug is generally administered subcutaneously but may be given at equal dosage intravenously if clinical conditions warrant or if vehicle volumes are too high to permit comfortable subcutaneous injection. In G-CSF refractory patients, combination therapy with SCF has been reported to be effective[533] but rarely used, because it also leads to mast cell activation with histamine release and anaphylactoid reactions. GM-CSF treatment results in large increases in eosinophils and monocytes, but not neutrophils.[575]

Side effects of G-CSF treatment are usually (but not always) mild and include bone pain, headache, and rashes. Other common but often asymptomatic findings include splenomegaly and osteopenia.[530,576] Splenomegaly has been reported in patients with SCN before and with G-CSF therapy.[530,576] Palpable splenomegaly, with a median spleen measurement of 2 cm below costal margin was recorded in 18.2% of untreated patients registered in the SCNIR. During the first year of G-CSF therapy, the incidence increased to 38.2% and remained at this level of occurrence (26.7% to 44.7%) through 10 years of therapy, with no trend to progression in spleen size on therapy.[530]

Of 128 SCNIR subjects analyzed in 2010,[577] including 40 children younger than age 21 years and 122 subjects receiving G-CSF, 46% of adults met criteria for osteopenia (t score −1), 9% met criteria for osteoporosis (t score <–2.5), and17.5% of children had low bone mineral density for age (Z score <–2.0). In children but not adults, bone mineral density was inversely related to duration of G-CSF therapy. The SCNIR recommends regular monitoring of bone density.[530] Rare patients have also been found to have vasculitis or glomerulonephritis, both before and during G-CSF therapy.[530]

The SCNIR has reported thrombocytopenia (platelet count $<50 \times 10^3/\mu L$) in 26 patients, including 17 with SCN.[530] Among the 19 patients receiving G-CSF, seven developed thrombocytopenia concurrent with conversion to MDS/AML. Thus development of thrombocytopenia in SCN patients requires thorough evaluation as a possible heralding sign of disease conversion.

Conversion to MDS/AML and bacterial sepsis remain the most serious complications of SCN. The predilection to acute leukemia was recognized before the availability of G-CSF,[535,536] when most affected children died early in life from severe infections. Now longer survival and G-CSF itself combine to produce, after 10 years of therapy, an ongoing 2.3% per year risk of developing AML or MDS that almost invariably progresses to AML.[512]

During long-term therapy with G-CSF, some SCN patients acquire mutations in the G-CSF receptor gene (*CSF3R*), particularly C-terminal truncation mutations that confer a clonal growth advantage.[578] Acquisition of these mutations is often, but not always, followed by evolution to myelodysplasia characterized by monosomy 7 and finally myeloid leukemia.[579-581] Acquired mutations in *CSF3R* have been detected in approximately 80% of SCNIR patients who developed MDS/AML, whereas mutations in the *FLT3, KIT,* and *JAK2* tyrosine kinase genes commonly found in de novo AML are uncommon.[581,582] *RUNX1* mutations appear most often upon evolution to AML,[583] but genome-wide analysis has revealed acquired mutations in multiple genes, including *CSF3R*, *LLGL2*, and *ZC3H18* in a subpopulation of progenitor cells early in the process, followed by mutations in known AML-associated genes (*RUNX1* and *ASXL1*) and chromatin remodelers (*SUZ12* and *EP300*) in leukemic clones.[584]

Some patients with SCN and *CSF3R* mutations have not progressed, and there are some who lost the mutated clone upon discontinuation of G-CSF therapy and reacquired it upon resumption of treatment.[581,585,586] Cytogenetic abnormalities, particularly monosomy 7, also precede and predict leukemic conversion. For this reason, yearly bone marrow surveillance, including karyotyping and chromosome 7 fluorescence in situ hybridization (FISH), should be performed on all patients with SCN, whether or not they are treated with G-CSF.[512,572,574] Although clonal cytogenetic abnormalities may spontaneously remit, their appearance should be considered a strong indication for HSCT, including use of a matched unrelated donor if necessary, because transplantation is more likely to be successful when undertaken before progression to MDS/AML.[587,588]

Recent studies by the SCNIR and the French Severe Chronic Neutropenia Study Group[512,545,579,589] have shed light on the incidence and some of the risk factors for sepsis and MDS/AML. Although early reports suggested a rising risk of MDS/AML after 10 years of G-CSF therapy,[579,589] longer follow-up study has shown the risk to be stable at 2.3% per year after 10 years of G-CSF

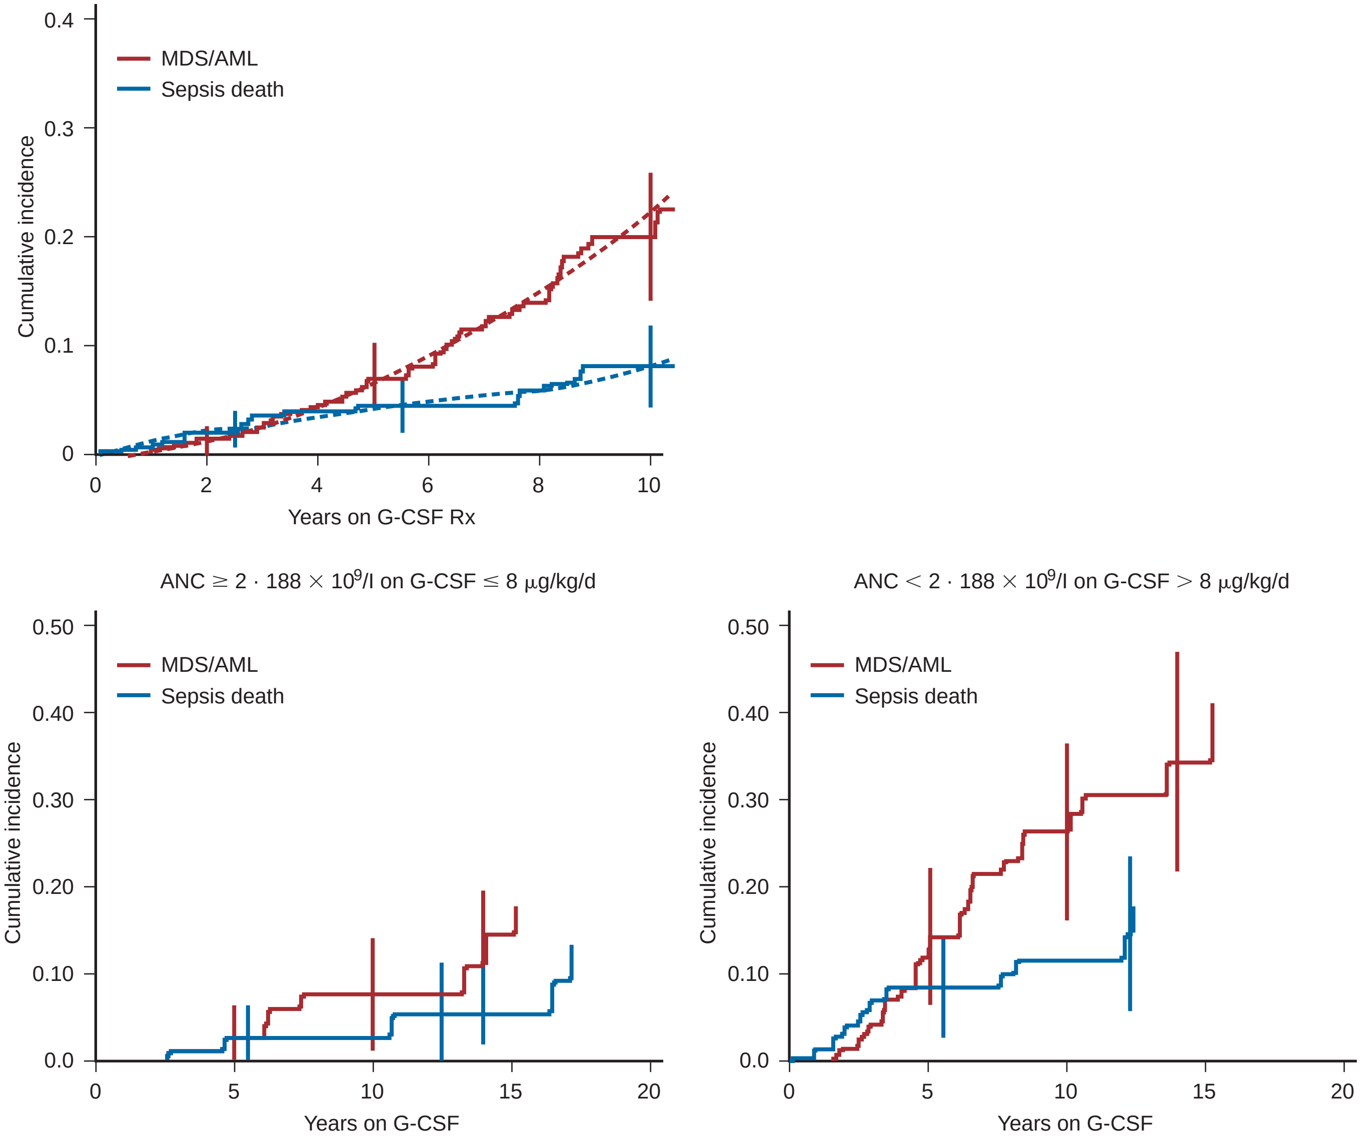

Figure 22-11 Cumulative incidence of MDS/AML and sepsis death in patients with SCN. *Upper panel:* Cumulative incidence (cumulative proportion experiencing each event as initial cause of failure, in patients at risk of each adverse event) for MDS/AML *(red)* and sepsis death *(blue)* by years on G-CSF therapy. Error bars show pointwise 95% confidence intervals. *Lower panels:* Cumulative incidence of MDS/AML and sepsis death in subgroups of patients with SCN. *Left,* Cumulative incidence of MDS/AML *(red)* and sepsis death *(blue)* among patients who achieved mean ANC ≥2.2 × 10^9 cells/μL at doses of G-CSF ≤8 μg/kg/day. *Right,* Corresponding cumulative incidence curves among patients who failed to achieve ANC ≥2.2 × 10^9 cells/μL despite doses of G-CSF >8 μg/kg/day. Error bars show pointwise 95% confidence intervals. *AML,* Acute myelogenous leukemia; *ANC,* absolute neutrophil count; *G-CSF,* granulocyte colony-stimulating factor; *MDS,* myelodysplastic syndrome. *(From Rosenberg PS, Zeidler C, Bolyard AA, et al: Stable long-term risk of leukaemia in patients with SCN maintained on G-CSF therapy.* Br J Haematol *150:196–199, 2010).*

therapy (Fig. 22-11).[512] The SCNIR analysis also identified a subgroup of patients with SCN at greatest risk for MDS/AML.[512,589] The high-risk group with a G-CSF dosage of 8 μg/kg/day or more and ANC less than 2188 cells/μL had a cumulative incidence at 15 years of 34% for MDS/AML and 15% for death from sepsis, compared to 15% and 5%, respectively, for the low-risk group (G-CSF dosage <8 μg/kg/day and ANC ≥2188 cells/μL) (see Fig. 22-11). Importantly, however, even the patients with the best responses to G-CSF were not free of risk for MDS/AML or even death from sepsis. Although data were not available for blood counts at the time of onset of sepsis, these patients had demonstrated ANCs over 1000 cells/μL while receiving G-CSF therapy, suggesting that they were either not fully adherent to the treatment[590] or that their granulocytes, although seemingly adequate in number, may have been limited in function.[591] For patients in the "worst responder" category of high G-CSF dosage requirements and low ANC on therapy, early transplantation should be considered, depending upon donor availability, but the indication is not as strong as for those already showing abnormal cytogenetics.

Analysis of *ELANE* gene mutations has also identified genetic risk factors for conversion to MDS/AML. In an SCNIR study of 188 patients with SCN and *ELANE* gene sequencing, 30 (16%) developed MDS/AML that was

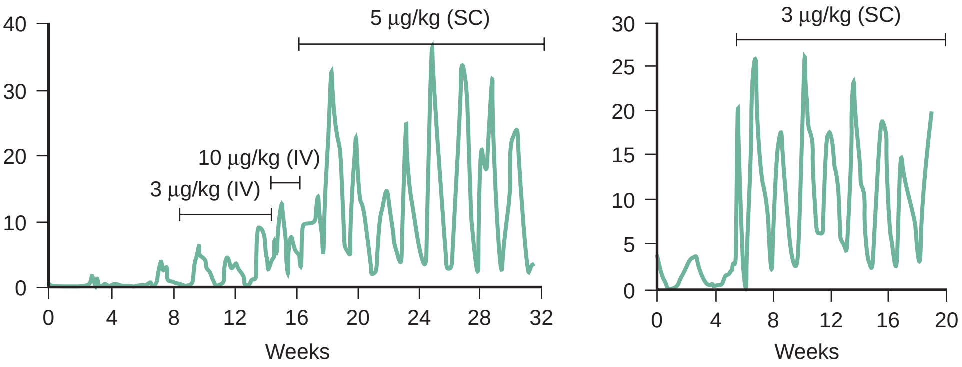

Figure 22-12 Absolute neutrophil counts in CyN and the response to administration of G-CSF. The cycling of neutrophil counts before and during therapy with the indicated doses of G-CSF is shown. Note the approximately 21-day cycle before therapy that is characteristic of CyN. With G-CSF therapy, the cycles shortened to approximately 14 days, peak neutrophil counts rose approximately 10-fold, and nadir neutrophil counts increased to ≥1000/µL. *(From Hammond WP, Price TH, Souza LM, Dale DC: Treatment of cyclic neutropenia with granulocyte colony-stimulating factor.* N Engl J Med *320:1306–1311, 1989.)*

associated with 25 different mutations, but clusters of MDS/AML cases were associated with mutations *C151Y, G214R,* and *S126L,* and both these and other mutations identified in single MDS/AML cases tended to be associated with higher G-CSF dosage requirements and poorer ANC responses.[545] On the other hand, there were no cases of MDS/AML in patients with mutations associated with both SCN and CyN phenotypes.

Cyclic Neutropenia. CyN is an AD disorder characterized by regular periodic oscillations approximately every 21 days in the number of peripheral blood neutrophils, with a nadir of less than 200 cells per µL (Fig. 22-12).[592,593] The incidence of CyN has been estimated at 0.5 to 1 case per million population.[533] During the neutropenic nadir of each cycle, patients may suffer from malaise, fever, oral and genital ulcers, gingivitis, periodontitis, and pharyngitis with local lymph node enlargement. Symptoms typically begin during the first year of life but may not present until adulthood. More serious complications can occasionally occur, including intestinal perforation with peritonitis, mastoiditis, and pneumonia. The severity of the infections tends to parallel the depth of the neutropenia, but some patients escape infections entirely during the neutropenic period. Many patients experience improvement in symptoms as they grow older. In these individuals, the cycles tend to become less noticeable as the neutrophil nadir rises to a more functionally adequate level. Although CyN is commonly viewed as a benign condition, 10% of patients in historical reviews have died of infectious complications.[593,594] Pneumonias and peritonitis, the latter complicated by clostridial sepsis, have been the most common causes of death.[592,593]

Oscillations in the rate of bone marrow production of neutrophils result in neutropenia with nadirs at intervals of 21 ± 3 days in the majority of patients. Neutrophil counts often fall to 0 at some time during the nadir and remain below 200 cells per µL for at least 3 to 5 days. In most patients, monocytosis occurs when neutrophil counts are at their lowest. In the recovery phase, the neutrophil counts rise, often into the low normal range, and monocyte counts drop. Oscillations are subtle in some individuals, particularly older patients, who instead have a pattern more consistent with chronic neutropenia. Oscillations in reticulocyte and platelet counts may parallel those seen for neutrophils,[593,595] hence the alternative term *cyclic hematopoiesis,* but these other cell numbers range between normal and elevated levels and thus have no clinical impact. Marrow aspirates show highly variable morphology, depending upon the phase of the cycle. The myeloid series may show hypoplasia with “maturation arrest” at the myelocyte stage during the declining phase of the neutrophil oscillation, but normal or hyperplastic myelopoiesis during neutrophil recovery.

Patients with CyN have been shown to have mutations in the *ELANE* gene, most often in exons 4 or 5, but not other genes associated with SCN.[409,410,596] How mutations in neutrophil elastase result in the cyclical production of neutrophils and other blood cells is not well understood. As discussed, both CyN and SCN are characterized by increased apoptosis of bone marrow neutrophil precursors,[546-549] probably because of an excessive unfolded protein response to mutant elastase.[411,412,550] Cycling may occur because of partial recovery of myelopoiesis stimulated by endogenous G-CSF production at the nadir, but with oscillation rather than homeostasis occurring as a result of the abnormal kinetics of the feedback loop.[597,598]

CyN must be distinguished from cyclic fevers without neutropenia[599] and from other forms of neutropenia, which can also produce less regular and lower amplitude variations in neutrophil counts. To establish the diagnosis of CyN, neutrophil counts should be monitored twice, or at least once, a week for 6 to 8 weeks. The genetic diagnosis can be confirmed by sequencing of the *ELANE* gene.

The management of patients with CyN includes careful attention to the identification and treatment of infections acquired when these patents are in a neutropenic phase. In general, fevers, upper respiratory symptoms, and cervical lymphadenopathy occurring during neutropenic episodes require no specific therapy. However, the physician must remain alert to symptoms suggesting a specific infection, particularly the sometimes fatal abdominal complications. Careful attention to oral and dental hygiene is important to minimize periodontal disease and ameliorate the discomfort of mouth sores. To prevent the development of severe infections and dental complications, G-CSF (filgrastim) therapy is recommended for patients with CyN with ANC nadirs consistently below 500 cells per μL.

G-CSF has been very effective in improving peripheral blood neutrophil counts in this disorder and alleviating the signs, symptoms, and risks associated with neutropenic nadirs.[530,566,576,596,600] Most patients still experience cycles, and in fact the amplitude of the cycling may increase but with shortened cycle periods and increased neutrophil counts at the nadir (see Fig. 22-7).[597,600] The dose of G-CSF required to maintain peripheral neutrophil counts in the normal range in most patients with CyN is usually 2 to 4 μg/kg/day, administered either daily or on alternate days.[567,589,601] Cases of MDS or leukemia have not been reported for patients with CyN, including those treated long term with G-CSF.[545,601]

Myelokathexis and WHIM Syndrome. Myelokathexis is an uncommon form of moderate to severe chronic neutropenia characterized by granulocyte hyperplasia in the bone marrow, which contains degenerating neutrophils with cytoplasmic vacuoles, prominent granules, and nuclear hypersegmentation with very thin filaments connecting pyknotic-appearing nuclear lobes.[602-604] Similar abnormalities can be seen in the majority of peripheral blood neutrophils. Eosinophils exhibit similar abnormal morphology, but lymphocytes, monocytes, and basophils appear normal,[603] although relative lymphopenia has been noted in some patients.[603] Recurrent warts and hypogammaglobulinemia (low IgG and occasionally low IgM and IgA) have often been reported in patients diagnosed with myelokathexis; hence the acronym *WHIM*.[605]

Recurrent sinopulmonary infections and other bacterial infections in WHIM syndrome probably reflect an increased susceptibility because of both neutropenia and hypogammaglobulinemia. However, early deaths related to infection have not been reported, and affected patients are capable of mobilizing increased numbers of neutrophils into the peripheral blood during infectious episodes.[604] Neutrophil function has generally been reported to be normal.

The genetic basis of WHIM syndrome was first identified as an AD truncating mutation in the cytoplasmic tail domain of the *CXCR4* gene, encoding chemokine receptor-4,[606] a G-protein–coupled receptor for *CXCL12,* (SDF-1). However, in other kindreds with wild-type *CXCR4* genes and probable AR inheritance, including one with homozygous mutations in *G6PC3*,[607] patients' leukocytes displayed similar marked enhancement of G-protein–dependent responses to *CXCR4* ligands.[608,609] Therefore the aberrant dysfunction of the *CXCR4*-mediated signaling constitutes a common biologic trait of WHIM syndromes with different causative genetic anomalies. As the interaction between *CXCR4* and *CXCL12* provides a key retention signal for neutrophils in the bone marrow,[40] myelokathexis has been suggested to result from retention of neutrophils in the marrow (*kathexis* means *retention*), where they undergo eventual apoptosis, evident in their diminished expression of the antiapoptotic factor *bcl-x*.[610]

The neutropenia and excessive granulocyte apoptosis of WHIM syndrome are partially corrected by G-CSF or GM-CSF therapy, with responses typically seen within 4 to 8 hours of administration.[604,610] Immunoglobulin levels also return to normal in patients treated with G-CSF.[604] Specific therapy aimed at the primary molecular defect has recently been reported, using the *CXCR4* antagonist plerixafor (formerly known as *AMD3100*) to correct the leukopenias of WHIM syndrome.[611,612]

Shwachman-Diamond Syndrome. Shwachman-Diamond syndrome, a rare multiorgan disease inherited as an AR trait, includes clinical findings of neutropenia, pancreatic exocrine insufficiency, short stature, and metaphyseal chondrodysplasia.[613-615] This disorder is also described in Chapter 8 with a more detailed discussion of its genetics and pathophysiology. As in other bone marrow failure syndromes, patients are at risk for conversion to MDS/AML.[614] The pancreatic acini are largely replaced by fatty tissue with relative sparing of the pancreatic ducts and islets.[615,616] Growth failure and short stature are usually noted during the first or second year of life, and puberty is often delayed. Although the classic syndrome includes the triad of cytopenias, pancreatic dysfunction, and skeletal abnormalities, clinical presentations can be highly variable, including any number or none of these features.[614,617]

Patients may show symptoms in infancy with eczema, skin infections, and otitis media; pneumonia, osteomyelitis, and sepsis can also be seen. Pancreatic insufficiency typically manifests in early infancy with steatorrhea, weight loss, and failure to thrive. Later in childhood, pancreatic function may improve, rendering the clinical diagnosis elusive.[618] Levels of serum trypsinogen, pancreatic isoamylase, and stool elastase are generally low but not specifically diagnostic,[614] and normal ranges are not well established for infants. Computed tomography scanning may reveal pancreatic lipomatosis. Mild abnormalities of the liver including hepatomegaly or elevated serum liver enzyme, are seen in 50% to 75% of younger patients, but they are usually mild and tend to resolve with age.

Common skeletal abnormalities include short stature and bone dysplasia evident in delayed appearance (but subsequent normal development) of secondary ossification centers as well as metaphyseal widening, first evident in the ribs (which appear short, with flared ends) and later in the proximal and distal femur.[614] Other skeletal findings include clinodactyly, syndactyly, pes cavus, kyphosis, scoliosis, osteopenia, vertebral collapse, slipped femoral epiphysis, and supernumerary digits.[616]

Neutropenia is the most common hematological manifestation of the syndrome, but some patients present with GI or skeletal problems and virtually normal blood counts.[613,614,617] Neutrophil counts fall below 1000 cells per μL in approximately two thirds of patients, with no reciprocal monocytosis, but low counts may be intermittent. Some patients also have defects in chemotaxis or in numbers or function of B, T, and NK cells that may increase susceptibility to pyogenic infection.[619,620] Shwachman-Diamond syndrome leukocytes may also show telomere shortening, which can overlap in severity with that observed in other bone marrow failure syndromes, even including dyskeratosis congenita.[617,621] Anemia (normocytic or macrocytic) is common, and one fourth of patients have mild to moderate thrombocytopenia.[616,618,622] Bone marrow studies have generally shown some degree of myeloid hypoplasia[616,618,622] but are nondiagnostic.

The diagnosis of Shwachman-Diamond syndrome may be based on a combination of neutropenia, possibly other cytopenias, pancreatic insufficiency, and skeletal anomalies. Around 90% of patients who meet the clinical criteria harbor mutations in the Shwachman-Bodian-Diamond syndrome gene, *SBDS*,[622,623] which functions in ribosomal biogenesis and other cellular processes.[613] With increased detection of variant forms of the syndrome by genetic testing, a wider clinical phenotype has been recognized. In a study from the North American Shwachman-Diamond Registry,[617] pancreatic lipomatosis was found in 22 of 23 patients, low fecal elastase in 14 of 17 patients, and low serum trypsinogen or pancreatic isoamylase in all 18 patients tested. Of 31 patients with clinical assessments, 26 had failure to thrive and 17 had diarrhea or steatorrhea; 17 had congenital anomalies. Neutropenia was the most common hematologic abnormality at presentation (77%), but two patients had isolated thrombocytopenia, three had severe anemia, and five had no cytopenias.

Treatment includes pancreatic enzyme replacement, which does not improve the neutropenia or dwarfism. Steatorrhea tends to diminish with time, although pancreatic insufficiency persists.[624] The incidence of bacterial infections can vary among patients, generally depending upon the ANC. Administration of G-CSF increases the neutrophil count to the normal range[616,622] and should be used in patients with persistently severe neutropenia or with recurrent or life-threatening infections.

Patients with Shwachman-Diamond syndrome may develop aplastic anemia, MDS, or leukemia, although usually later in life than patients with Fanconi anemia or SCN.[569,625] These complications generally require treatment by HSCT.[614] There are only very rare reports of solid tumors.[626-628] A study from the French Severe Chronic Neutropenia Registry reported a 24% 20-year cumulative risk of aplastic anemia and MDS/AML in 102 patients; young age (<3 months) at first symptoms and low hematologic parameters both at diagnosis and during follow-up study were associated with severe hematologic complications.[569] Because acquisition of a structural chromosomal abnormality, most commonly isochromosome i(7q) followed by del(20q), often precedes conversion to MDS,[616,622,629,630] regular blood counts are recommended, and bone marrow examinations should be performed annually or more often in the face of evolving peripheral blood or cytogenetic findings.[616] Cytogenetic abnormalities may be transient or unaccompanied by marrow dysplasia, so it remains unclear whether high-risk clonal aberrations constitute indications for HSCT.[614,616]

Albinism-Neutropenia Syndromes

This group of rare primary immunodeficiency syndromes derive from AR defects in the biogenesis or trafficking of lysosomes and related late endosomal organelles.[631,632] As a result, they share varying degrees of overlap in phenotype, including defects in formation of melanosomes (hence partial albinism), abnormal platelet function, and immunological defects involving not only neutrophil number but also the function of neutrophils, B lymphocytes, and cytotoxic T lymphocytes. They share a high risk of hemophagocytic lymphohistiocytosis (HLH) because of defects in T and NK cells.[633] The partial albinism may be sufficiently subtle to require microscopic examination of hair for irregular, clumped melanosomes.

CHS is a rare genetic disorder characterized by partial oculocutaneous albinism, giant lysosomes in many cell types including granulocytes, and neuropathy.[634] Most patients have moderate neutropenia, apparently because of ineffective granulopoiesis, and a high risk of HLH. CHS is described in detail later in this chapter.

Hermansky-Pudlak syndrome, another rare AR disease characterized by oculocutaneous albinism, is best known for associated platelet defects (see Chapter 8). One subtype, Hermansky-Pudlak syndrome type 2, also includes neutropenia and decreased numbers of NK cells, leading to increased susceptibility to infections and HLH.[635,636] The *AP3B1* gene responsible for this disorder,[637] as well as for CyN in grey collie dogs,[638] encodes an adapter protein involved in shuttling granule proteins, including neutrophil elastase, and thus may provide a connection to the molecular pathology of SCN[638] and HLH.[633]

Griscelli syndrome type 2, falls within the spectrum of Griscelli syndrome subtypes that share a phenotype of hypomelanosis with varying degrees of neurological impairment and immunodeficiency.[639] The type 2 variant is characterized by neutropenia, hypogammaglobulinemia, partial albinism, and a predisposition to HLH.[633,640] It is caused by mutations in the *RAB27A* gene,[641] which encodes a small GTPase that serves as a key effector of granule exocytosis.[642]

Cohen syndrome is an AR condition that includes neutropenia, pigmentary retinopathy, microcephaly, intellectual deficiency, and facial dysmorphism.[643] The gene responsible for Cohen syndrome, *COH1* (also termed *VPS13B*), shares homology to a yeast protein that functions in vesicular sorting and intracellular protein trafficking. A case with congenital neutropenia, pigmentary retinopathy, and only subtle dysmorphism due to splicing mutations in *VPS13B* indicates a wider phenotype and a need to consider this gene in the evaluation of patients with neutropenia and retinopathy.[643a]

A single Mennonite family has been described with severe chronic neutropenia combined with short stature, albinism, coarse facial features, and recurrent bronchopulmonary infections by *Streptococcus pneumoniae*.[644] This syndrome is caused by defects in the endosomal adaptor protein p14, which is involved in MAPK signaling to late endosomes.[645]

Familial Benign Neutropenia

Familial benign neutropenia is a nonspecific descriptive diagnosis indicative of mild neutropenia with no tendency to increased infection. AD transmission has been identified in some familial cases.[646] Although “familial benign neutropenia" has been described in Yemenite Jews,[647] and in persons of German, French, American, and South African descent,[648] these kindreds were investigated before the era of current immunological and molecular diagnostic tools, so they might now be classified with more specific diagnoses. For example, "benign ethnic neutropenia" in persons of African origin has recently been found to result from the Duffy negative genotype.[508]

Other Causes of Neutropenia Caused by Intrinsic Defects in Myelopoiesis

Congenital or acquired bone marrow failure syndromes can occasionally present with isolated neutropenia. Fanconi anemia and dyskeratosis congenita should usually be recognized by other features associated with these disorders (see Chapter 8). Acquired aplastic anemia and MDSs may occur as primary processes, or as complications of bone marrow failure syndromes. Mild chronic neutropenia is a minor feature of monocytopenia and mycobacterial infection (MonoMAC) syndrome[649] discussed later in this section.

Neutropenia Associated with Immune Dysfunction

Primary disorders of immunoglobulin production have been associated with neutropenic syndromes.[650-652] One third of males with X-linked agammaglobulinemia have neutropenia at some time during the course of their disease.[650,652] Persistent or CyN is common in patients with the hyper-IgM immunodeficiency syndrome, which in many instances appears to be secondary to the formation of autoantibodies.[650,652,653] Immunoglobulin replacement therapy abolished the neutropenia in some but not all of these patients.[654] AIN and other autoimmune cytopenias can also be seen in common variable immunodeficiency and isolated IgA deficiency.[650,651,653]

Autoimmune lymphoproliferative syndrome (ALPS) reflects a family of defects in lymphocyte apoptosis. The syndrome includes lymphadenopathy, splenomegaly, and a variety of autoimmune disorders including immune thrombocytopenia, anemia, and neutropenia.[655,656] Neutropenia associated with ALPS tends to be chronic, and because of the unique pathophysiology of the underlying disorder, represents one of the few forms of neutropenia treated by immunosuppression with corticosteroids or mycophenolate mofetil.

Cartilage hair hypoplasia, an AR disorder found in the Amish population, is characterized by short-limbed dwarfism, fine hair, moderate neutropenia (100 to 2000 cells per μL), and impaired cell-mediated immunity.[657,658] The disorder arises from mutations in the noncoding RNA gene *RMRP*,[659] which provides the RNA subunit of the pancreatic ribonuclease mitochondrial RNA processing enzyme, a complex involved in multiple cellular RNA processing events.[660] G-CSF therapy has been reported to be effective in a single patient who also had an antineutrophil antibody[661]; bone marrow transplantation has corrected both the immunologic defects and neutropenia.[662]

Schimke immuno-osseous dysplasia, a rare AR syndrome with variable expressivity, is characterized by spondyloepiphyseal dysplasia, steroid-resistant nephritic syndrome, lymphopenia with defective cellular immunity, neutropenia, and other cytopenias.[663,664] Vaso-occlusive processes, including cerebral and generalized atherosclerosis, are a life-limiting complication in the more severely affected patients.[665] The disorder is associated with mutations in the gene *SMARCAL1*, although the genetics may be heterogeneous.[666,667] The immunodeficiencies and cytopenias can be treated with HSCT[668]; neutropenia, seen in 40% of patients, responds to G-CSF therapy.[664]

Poikiloderma with neutropenia, Clericuzio type, is a rare AR genodermatosis characterized by early onset poikiloderma followed by pachyonychia, palmoplantar hyperkeratosis, and skeletal defects, as well as variable degrees of neutropenia and possible predisposition to malignancy.[669,670] The gene mutated in this disorder, *USB1* (also termed *C16orf57*),[669,671,672] encodes a putative phosphodiesterase responsible for oligoadenylation of spliceosomal small nuclear RNA U6.[673] Mutations in *USB1* have also been identified in patients with Rothmund-Thomson syndrome (a phenotypically similar but distinct genodermatosis) and dyskeratosis congenita.[670,672]

Neutropenia Associated with Metabolic Diseases

Significant neutropenia, often with relative monocytosis, occurs in Barth syndrome, a distinctive X-linked disorder caused by mutations in the *TAZ* gene, which encodes tafazzin, a phospholipid-lysophospholipid transacylase involved in the maintenance of mitochondrial cardiolipin.[674-676] Clinical features include dilated cardiomyopathy, growth retardation, and 3-methylglutaconic aciduria.[677,678] Affected boys develop symptoms in infancy or childhood, and neutropenia can precede the development of cardiac abnormalities. Neutrophil counts are variable and occasionally cyclic, ranging from nearly normal to very low, with recurring and sometimes life-threatening bacterial infections occurring in the most severely affected.[676] Bone marrow shows maturation arrest at the myelocyte stage, with myeloblasts and promyelocytes demonstrating abnormal mitochondria.[677]

Neutrophils in patients with glycogen storage disease type Ib (OMIM # 232220) are not only diminished in number, with neutrophil counts commonly less than 500 cells per μL,[679-681] but also functionally defective, with abnormalities reported in chemotaxis, respiratory burst activity, and bacterial killing.[682,683] The disorder derives from mutations in the glucose-6-phosphate transporter, encoded by the *SLC37A4* gene.[678] The defects in neutrophil survival and function are similar to those due to mutations in the myeloid-specific *G6PC3* gene.[558] Recombinant G-CSF has been effective in correcting the neutropenia and reducing serious infections in glycogen storage disease type Ib.[684] Prolonged use of G-CSF has not been associated with any increased risk of MDS/AML in this disease.[579,681]

Macrocytic anemia, often accompanied by neutropenia or thrombocytopenia, is a hematologic hallmark of Pearson syndrome, a rare and fatal congenital disorder involving not only the hematopoietic system but also the exocrine pancreas, liver, and kidneys.[685] The bone marrow shows normal cellularity but striking abnormalities that include vacuolization of erythroid and myeloid precursors, hemosiderosis, and ringed sideroblasts. A mitochondrial defect related to large deletions in mitochondrial DNA, whose integrity depends on a specific DNA polymerase, likely leads to impaired hematopoiesis.[686]

Neutropenia, usually accompanied by metabolic abnormalities including acidosis, ketosis, hyperammonemia, and hypoglycemia, can be a feature of organic acidemias such as propionic acidemia, methylmalonic acidemia, methylmalonic aciduria, and others.[687] Although these congenital disorders are usually evident in the first 10 days of life, variants can present in older children or adolescents. Diagnosis is based on screening of urine organic acids, followed by more specific metabolic or genetic testing. Disorders of cobalamin metabolism can present in the first months to years of life with neutropenia and are usually accompanied by macrocytic anemia and often by methylmalonic acidemia.[688]

Neutropenia Caused by Extrinsic Factors

Infection. The most common cause of transient neutropenia in childhood is viral infection. Viruses commonly causing acute transient neutropenia include influenza A and B, adenovirus, respiratory syncytial virus, enteroviruses, human herpes virus 6, measles, rubella, and varicella.[689-691] Neutropenia develops during the first 24 to 48 hours of the illness and may persist for 3 to 6 days. This period usually corresponds to the time of acute viremia and may relate to virus-induced redistribution of neutrophils from the circulating to the marginated granulocyte pool, sequestration, or increased neutrophil utilization after tissue damage caused by the viruses.[692,693]

Both transient and chronic neutropenia occur with Epstein-Barr virus infection[694,695] and may be related to splenomegaly, direct infection of progenitors,[696] and antineutrophil antibodies.[697,698] Cytomegalovirus (CMV) infection and anti-CMV therapies may cause neutropenia in the setting of perinatal infection or immune suppression (particularly HSCT or solid organ transplant) but can also affect the immunocompetent.[699-702] Parvovirus B19 and hepatitis A and B may also cause neutropenia,[703,704] although they are more commonly associated with pure red cell aplasia and multiple cytopenias, respectively.

Leukopenia, either transient or chronic, is also common in patients with HIV infection as a result of multiple causes, including antiretroviral drugs, cellular immune dysfunction, ineffective hematopoiesis, antineutrophil antibodies, B_{12} or folate deficiency, and hypersplenism.[705-708]

Significant neutropenia may occur during typhoid, paratyphoid, tuberculosis, brucellosis, tularemia, and rickettsial infections.[689,709-712] The mechanisms responsible for neutropenia in these conditions remain ill-defined. During periods of relapsing fever caused by acute malaria, the apparent neutropenia may be secondary to increased neutrophil margination in the spleen.[713,714]

Neutropenia in patients with bacteremia and endotoxemia may result from excessive destruction of neutrophils with depletion of the bone marrow reserve pool and constitutes a dire prognostic sign, particularly in newborns.[715] This consumption can occur after phagocytosis of microbes, from the release of metabolites of arachidonic acid, or from activation of the complement system through either the alternate or classic pathway. The resultant generation of the chemoattractant C5a induces neutrophil aggregation and leads to the formation of leukoemboli, which adhere to and damage endothelial surfaces in the pulmonary capillary bed. Complement-mediated neutropenia may also occur transiently during hemodialysis, during continuous-flow leukapheresis, and after burn injury.[716-719]

Newborns with sepsis may benefit from granulocyte transfusion[720,721] or G-CSF,[722,723] but clinical trials have not yet provided compelling evidence for benefit from either modality.[721,724]

Drug-Induced Neutropenia. Drug-induced neutropenia, defined as an idiosyncratic reaction to the offending drug,[725-739] excludes disorders in which other cell lines are perturbed (e.g. drug-related aplastic anemia) and the predictable neutropenias observed with anticancer therapy. Idiosyncratic reactions tend to develop more often in women than in men and more often in older than in younger persons.[729]

In its most serious form, drug-induced agranulocytosis, neutrophil counts reach levels below 200 cells/μL, with high morbidity (e.g. deep tissue infection and sepsis) and mortality rates as high as 5%.[725] Most deaths occur in patients who are elderly or have metabolic complications such as shock or renal failure.

Almost any drug can cause neutropenia; Table 22-9 lists the agents most commonly associated with isolated, idiosyncratic neutropenia or agranulocytosis. Drugs reported to have been associated with agranulocytosis have been extensively reviewed.[725,726,728,731,736-738] The most common drug classes include antiinflammatories, particularly aminopyrine and sulfasalazine; antimicrobial agents, particularly trimethoprim and sulfamethoxazole; antithyroid drugs; antipsychotics such as clozapine and phenothiazines; and others such as deferiprone and rituximab (see Table 22-9).

Although the underlying mechanisms for most drug-induced neutropenias are unknown, most studies suggest that they can be classified as leading to toxic suppression of neutrophil formation or immune destruction of mature cells.[728,730,737,738] Neutropenia resulting from myelosuppression is usually insidious in onset and may be asymptomatic. Oral mucositis may be the first clinical sign before infectious complications. Individual differences in drug pharmacokinetics can lead to toxic levels of the drug or metabolites in the marrow microenvironment. For example, whereas neutropenia can be observed in any patient taking sulfasalazine, individuals who are slow acetylators show much greater toxicity than do those who are fast acetylators.[736] Alternatively, a susceptible patient's myeloid precursors may be abnormally sensitive to typical drug concentrations, as observed in neutropenia that can appear 20 to 40 days after starting phenothiazines.[728]

Drugs can also induce immune-mediated peripheral destruction of neutrophils by several mechanisms. In one,

TABLE 22-9 Partial List of Drugs Causing Idiosyncratic Drug-Induced Neutropenia*

	Possible Mechanism		
Drug	**Direct Suppression**	**Metabolite Suppression**	**Immune Destruction**
Antiinflammatory			
Aminopyrine			X
Ibuprofen			X

*Partial list of agents capable of causing idiosyncratic drug-induced neutropenia. Italics indicate the drugs with the highest relative risk of neutropenia and agranulocytosis. The mechanism, when unknown, has been left blank; some of the indicated mechanisms are not well established.

the drug serves as a hapten in promoting the synthesis of antibodies that are capable of destroying mature neutrophils. Aminopyrine, penicillin, propylthiouracil, and gold can cause neutropenia by this mechanism.[728,732,735,738] Alternatively, the drug can elicit the formation of circulating immune complexes that attach to the surface of the neutrophil and lead to its destruction, as in the case of quinidine. In addition, immunologic changes induced by drugs can suppress granulopoiesis. For example, activation of both cellular and humoral immune responses has been reported to impair myelopoiesis after therapy with quinidine and phenytoin, respectively.[730,738] Immune-mediated neutropenia is characterized by abrupt onset, often with fever, chills, and prostration, occurring 7 to 14 days after the first use of the drug or immediately after reexposure. Transient, usually mild, neutropenia may follow treatment of immune thrombocytopenia with intravenous immunoglobulin.[740]

The duration of drug-induced neutropenia is highly variable. Myelosuppressive drug reactions may last from a few days to months or years, whereas immune-mediated reactions usually last for 6 to 8 days. Once neutropenia occurs, the most important therapeutic action is, of course, to withdraw all drugs that are not absolutely essential, particularly those most highly associated with neutropenia. G-CSF therapy may hasten neutrophil recovery slightly, but evidence-based data are lacking to justify its routine use[548,741,742]; therefore the clinical indication is questionable unless the patient has a severe infection. During recovery from drug-induced neutropenia, with or without G-CSF therapy, rebound leukocytosis can occur and is accompanied by a left shift in the peripheral blood and bone marrow myeloid series with occasional circulating immature leukocytes.

Autoimmune Neutropenia. AIN can occur as an isolated process, as a manifestation other autoimmune diseases, or as a secondary complication of infection, drugs, or malignancy.[528,741,743] In primary AIN, low circulating neutrophil counts are the only hematological finding, and associated diseases or other factors that cause neutropenia are absent. The peak incidence of AIN occurs in infants and young children,[744,745] where it is a generally benign disorder that remits spontaneously, as discussed in the following section. Many cases of chronic idiopathic neutropenia in children and adults are now recognized as secondary to more generalized autoimmune disorders (Box 22-5).

Patients with AIN may have highly (and rapidly) varying neutrophil counts, ranging from the mild neutropenia to agranulocytosis. Monocytosis is common. Bone marrow examination generally shows normal to increased cellularity with myeloid hyperplasia and normal to increased numbers of mature neutrophils, although diminished neutrophils or maturation arrest at earlier stages of differentiation can also be seen.[528,741,743] Mild splenomegaly is occasionally present. The incidence of pyogenic infection is not always related to the degree of neutropenia[514,528] and is generally limited to cutaneous and respiratory infections. Serious infections are generally uncommon. Spontaneous remissions resolve the

process in most infants, but occur less commonly in older children (discussed later).

Neutrophil-specific cell surface antigens identified as targets of autoantibodies include human neutrophil antigen (HNA) 1a, formerly termed *NA1*; HNA-1b, formerly NA2; and HNA-2, formerly NB1.[348,746] The HNA-1a and HNA-1b antigens are glycosylated isoforms of the neutrophil immunoglobulin receptor FcγIIIb (CD16) (see Table 22-6), and the HNA-2 antigen is CD177, the counter-receptor for PECAM-1.[747] Mechanisms that trigger autoantibody production are unknown. In children, primary AIN is usually associated with HNA-allele–specific antibodies, but secondary AIN may be associated with pan-FcγRIIIb antibodies.[748]

The neutropenia of AIN is presumed primarily to be caused by peripheral destruction of antibody-coated neutrophils, which may be also be augmented by the deposition of C3. Phagocytosis of neutrophils in the spleens of patients with AIN has been observed.[749] In some cases, antineutrophil antibodies also appear to interfere with myelopoiesis.[750-752] Impairment of phagocytosis, respiratory burst activity, and adhesion by neutrophil-directed antibodies has also been observed, which may contribute to the risk of infection in AIN.[750,752,753]

Antineutrophil antibodies can be detected by direct or indirect granulocyte immunofluorescence tests (analogous to the direct and indirect antiglobulin tests for erythrocyte antibodies but usually performed by flow cytometry) or by granulocyte agglutination tests.[347,348,754,755] Granulocyte agglutination is less sensitive but may be useful for detecting neutrophil-binding immune complexes in Felty syndrome.[752] All of these tests are subject to false positive results from anti-HLA antibodies or nonspecific binding of immunoglobulins to neutrophil FcRs, as well as false negative results caused by high background levels of bound immunoglobulins. Because of the limited sensitivity and specificity of these assays, even in combination, laboratory tests for antineutrophil antibodies are neither necessary nor sufficient to make the diagnosis of AIN, and their interpretation depends on the specific clinical setting.

Importantly, the standard laboratory test for antineutrophil cytoplasmic antibody does not detect antibodies responsible for AIN.

Treatment of patients with immune neutropenia includes the judicious use of appropriate antibiotics for bacterial infections, plus antimicrobial mouthwashes and regular dental hygiene for mouth sores or gingivitis. Infections tend to be less common in immune neutropenia than with the corresponding degree of neutropenia from other causes, probably because granulopoiesis is in most cases intact and tissue delivery of neutrophils is greater than that with equivalent neutrophil levels caused by impaired production. Prophylactic administration of trimethoprim/sulfamethoxazole may be also helpful for management of recurrent minor infections, although there are no controlled studies addressing the efficacy of this approach.

For definitive therapy, administration of G-CSF starting at low dosages of 1 to 2 μg/kg/day has been successful in increasing the neutrophil count to the normal range or even higher in patients with primary AIN, including secondary immune neutropenia and Felty syndrome.[743,744,756,757] The initial response is usually apparent within days of starting therapy but may require up to 2 weeks. Patients with normal or high ANC during therapy may be weaned to a very low dosage or administration of G-CSF on alternate days. The incidence of bone pain appears to be higher in AIN than in hypoproductive neutropenia, probably because of expansion of the already hyperplastic bone marrow. Because most patients with immune neutropenias do not suffer serious infectious complications, G-CSF therapy should be reserved for the few with serious or recurrent infections or with multiple hospitalizations for febrile neutropenia. When used for AIN and other forms of acquired neutropenia, G-CSF is not associated with development of MDS/AML.

Intravenous immunoglobulin administration can result in normalization of the neutrophil count, but efficacy is variable and often short-lived.[743,744,756] Corticosteroids can raise the neutrophil count but may actually increase the risk of serious infection. Similarly, splenectomy can provide transient benefit that is offset by the risk of sepsis, and the procedure is limited to conditions with clinically significant splenomegaly such as Felty syndrome.[758]

T-cell large granular lymphocyte leukemia (LGL), a clonal disorder of cytotoxic T lymphocytes most common in the elderly, often presents as severe chronic neutropenia with or without accompanying anemia.[547,759] LGL-associated neutropenia, which overlaps clinically with Felty syndrome, may derive from either immune complex– or cell-mediated mechanisms and generally responds to a combination of immunosuppressive and cytotoxic therapy for the underlying disease and G-CSF for the neutropenia.[547]

Neutropenia can be seen as part of a broader spectrum of disease in a variety of other acquired disorders of the immune system. Autoimmune diseases such as systemic lupus and rheumatoid arthritis can be associated with antibody or immune complex-mediated destruction of neutrophils or their precursors.[760] Felty syndrome refers specifically to neutropenia in association with splenomegaly and seropositive rheumatoid arthritis; there is considerable pathophysiologic overlap between Felty syndrome and rheumatoid arthritis–associated LGL.[761] Therapy with G-CSF is effective but may precipitate flares of the underlying disease[762,763]; splenectomy may be effective, as discussed previously.

Chronic Benign Neutropenia and Autoimmune Neutropenia of Childhood. Most cases of what was termed chronic benign neutropenia of infancy and childhood are now believed to represent an AIN that has parallels to childhood idiopathic thrombocytopenic purpura.[743,744,756,764] AIN of childhood occurs predominantly in children younger than 3 years (Box 22-6). The median age of presentation is 8 to 11 months, with a range of 2 to 54 months.[743,744,756,764] There is a slight female predominance. Although AIN of childhood is the most common cause of chronic neutropenia in the pediatric age group, it is still a relatively uncommon diagnosis, with an incidence of approximately 1 in 100,000 children per year.[511,765] However, this figure is probably an underestimate because of the generally benign course of this disorder.

Box 22-6 **Summary of Autoimmune Neutropenia of Childhood**

CONSIDERABLE OVERLAP WITH CHRONIC BENIGN NEUTROPENIA OF CHILDHOOD

Incidence	Most common cause of chronic neutropenia in infancy and childhood; incidence ≥1 per 100,000 children per year.
Clinical features	Median age of diagnosis is 8-11 months of age (range 3-38 months). Relatively minor infections (otitis media, gingivitis, upper respiratory tract, skin) occur with an increased frequency only in some patients and respond well to antimicrobial therapy. Rare patients (usually young infants) have pneumonia or sepsis.
Laboratory evaluation	Median absolute neutrophil count at time of diagnosis ≈200 neutrophils/μL (range 0-500 cells/μL). Hemoglobin, platelet count generally normal. Antineutrophil antibodies can be detected in many patients and are often directed to human neutrophil antigen (HNA) 1 (FcγRIII). Bone marrow test (if performed) shows normal to increased myelopoiesis, sometimes with a decrease in mature neutrophils or maturation arrest at earlier stages.
Therapy	Antibiotics for acute infection; prophylactic antibiotics may be helpful in some patients with recurrent otitis media. Consider use of granulocyte colony-stimulating factor only in the event of serious infection, very frequent minor infections, or very frequent precautionary emergency room visits or admissions.
Prognosis	Excellent. Although the ANC often remains below 500 cells per μL for 12 or more months, spontaneous remission occurs in almost all patients (median of 20 months, range 6-54 months).

The presenting ANC is often in the severe range (<200 cells/μL), usually with a relative monocytosis and/or eosinophilia. Transient increases in circulating neutrophil counts can occur in response to infection. Other peripheral counts are normal for age. Mild thrombocytopenia has been reported,[766] but the presence of other autoimmune cytopenias more likely represents Evans syndrome (see Chapter 13), which is more likely to become chronic and to be associated with underlying immunodeficiency disorders or ALPS.

Antineutrophil antibodies can be detected in many patients by repeated testing with a combination of immunofluorescent and agglutination assays,[754,756,764,767] but absence of detectable antibody does not exclude the diagnosis, and a positive result does not exclude congenital neutropenia.[540] Bone marrow examination generally shows normal to increased cellularity with myeloid hyperplasia and normal to increased numbers of mature neutrophils.

Bacterial infections in AIN of childhood are generally mild (e.g., skin infections, otitis media, gingivitis) and responsive to standard antibiotics.[511,750,768] Cellulitis involving the labia majora was seen in 23% of 26 girls with AIN in one series, often the result of *Pseudomonas aeruginosa*.[511] Pneumonia, sepsis, and meningitis have been reported only occasionally in infants with AIN.[750] Spontaneous remission occurs in almost all patients, with neutropenia persisting for a median duration of 20 months.[768] Children younger than 9 months of age at the time of diagnosis may recover normal peripheral neutrophil counts more rapidly.[766] With increasing age, spontaneous remission becomes less likely.

Febrile episodes should be managed aggressively in the initial period before the diagnosis of childhood AIN is established, including the use of broad-spectrum parenteral antibiotics. However, once the diagnosis is definite and the patient has had no serious infections, subsequent febrile illnesses can be managed more conservatively if clinically warranted. Prophylactic trimethoprim/sulfamethoxazole can be helpful for children with recurrent otitis media and other minor infections. Administration of G-CSF results in an increased peripheral neutrophil count in childhood AIN and is the treatment of choice for the rare child with AIN who manifests very severe or recurrent major infections.[744,756,769] G-CSF doses of 1 to 2 μg/kg/day or less are usually effective, and responses are typically seen within days. Steroids and intravenous gamma globulin have also been used, but have limited efficacy, as discussed above.

Neonatal Immune Neutropenias

Immune-mediated neutropenia in the newborn may be isoimmune because of maternal immune response to fetal alloantigens or maternal autoimmune as a result of passive transfer of maternal autoantibody.

Neonatal isoimmune neutropenia, an immunologic disorder analogous to Rh hemolytic disease, results from maternal sensitization to fetal neutrophils bearing antigens that differ from the mother's. Maternal IgG antibodies cross the placenta and result in an immune-mediated neutropenia that can be severe and lasts from several weeks to as long as 6 months.[348,745,770] The infant bone marrow demonstrates myeloid hyperplasia, usually with depletion of mature neutrophil forms.

Neutrophil antibodies are found in the serum of the mother and the infant and are often directed to the neutrophil-specific HNA antigen system.[746] The HNA-1 antigens most often responsible are isotypes of the neutrophil Fcγ receptor IIIb (see Table 22-6). Affected infants can be asymptomatic or develop omphalitis, cutaneous infections, pneumonia, sepsis, and meningitis. Since neonatal sepsis can be itself associated with profound neutropenia, the underlying immune-mediated neutrophil destruction may not be appreciated immediately in affected newborns who have signs of sepsis.

The initial management of neonatal isoimmune neutropenia should include parenteral antibiotics, even if signs of infection are absent, because of the association of neutropenia with neonatal sepsis. Intravenous γ globulin may sometimes be effective in increasing the neutrophil counts.[771,772] Treatment with G-CSF starting at 5 to 10 μg/kg/day intravenously should be considered for very profound neutropenia or when serious infections develop in infants with isoimmune neutropenia.[745,773,774]

Neonatal immune neutropenia can also occur in infants of mothers with AIN. Transplacental passage of an IgG antineutrophil antibody can react with the infant's neutrophils bearing the inciting antigen and result in a profound neutropenia lasting 2 to 4 weeks.[745,775] Treatment is similar to that for isoimmune neutropenia. Leukoagglutinating antibodies directed against HLA antigens are commonly found in multiparous women and their newborn children's sera[776,777]; however, these antibodies are not associated with neutropenia and thus need to be distinguished from neutrophil-specific antibodies in laboratory assays.[754,770]

Nutritional Deficiencies. Ineffective granulopoiesis is part of the megaloblastic marrow pathology observed in patients with nutritional deficiencies of vitamin B_{12} or folic acid.[778] Neutropenia also occurs with severe protein-calorie malnutrition, as in anorexia nervosa[779] and marasmus. Neutropenia and marrow megaloblastosis have also been observed in copper deficiency[780] Notably, these nutritional deficiencies do not cause isolated neutropenia; anemia is virtually universal, and thrombocytopenia is an occasional additional finding.

Reticuloendothelial Sequestration. Splenic enlargement caused by portal hypertension, intrinsic splenic disease, or splenic hyperplasia can lead to neutropenia that is usually accompanied by similar degrees of thrombocytopenia and anemia. The neutropenia is usually mild and may be ameliorated by successful treatment of the underlying disease. In selected situations, splenectomy may be necessary to restore the neutrophil count to normal.

Bone Marrow Infiltration. Malignancies such as leukemia, lymphoma, and solid tumors that infiltrate the bone marrow result in a myelophthisic picture, producing leukoerythroblastic peripheral blood smears with neutropenia that is usually accompanied by other cytopenias. Tumor-induced myelofibrosis may further reduce the peripheral blood neutrophil count. Neutropenia can also result from bone marrow involvement in granulomatous infections, lysosomal storage disease, or osteopetrosis.[212,781,782]

Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia represents a group of disorders that by definition are poorly understood and cannot be placed in any of the previously named categories.[547,574] Investigation of the mechanism of neutropenia has suggested that in some cases, decreased or ineffective production of neutrophils may be the result of excessive apoptosis, such as in congenital neutropenia.[783] Overall, the clinical features, bone marrow findings, and natural history of chronic idiopathic neutropenia are variable but generally milder than congenital neutropenia; it is likely that many of the cases described in older studies had antibody-mediated neutrophil destruction and normal bone marrow reserve. Treatment, when necessary, should be based on the severity of symptoms; G-CSF has proven effective at lower doses than in SCN and without any reported increase in risk of MDS/AML.[530]

Evaluation of the Patient with Neutropenia

The basic approach to a patient with neutropenia (Fig. 22-13)[574] includes a history and physical examination with emphasis on: (1) related phenotypic abnormalities; (2) determination of whether bacterial infection is present (including evaluation of gingiva and perineum); (3) evaluation of lymphadenopathy, hepatosplenomegaly, and any other signs of an underlying associated chronic illness; and (4) history of recent infection and drug exposure. The frequency and duration of symptoms is important, and a history of periodontitis, dental abscesses, or tooth loss is particularly suspicious for significant chronic or recurrent neutropenia. The family history may reveal other individuals with recurrent infection. Unexplained deaths and the ethnic background in children younger than 1 year of age should be noted.

The duration and severity of the neutropenia and the presence or absence of significant other symptoms or physical findings greatly influence the speed and extent of laboratory evaluation. If the patient has isolated neutropenia, is asymptomatic, and other findings are absent, clinical observation for several weeks is usually the best approach. Any medications known or suspected to be associated with neutropenia should be discontinued. Any signs of an acute bacterial infection in a patient with moderate to severe neutropenia and fever calls for prompt evaluation and treatment, including the use of intravenous broad spectrum antibiotics.

Patients with persistent neutropenia should have white blood cell and differential counts obtained at least twice weekly for 6 to 8 weeks in order to evaluate for the periodicity of CyN. Direct and indirect antiglobulin tests should be performed to evaluate for the presence of red cell autoantibodies and quantitative serum immunoglobulins (IgG, IgA, and IgM, but not IgE) measured to detect

The central flow diagram presents a sequential series of steps in the evaluation, and the labeled arrows to each side indicate probable mechanisms or diagnoses followed by subsequent steps in the evaluation. *Severe phenotype* refers to a history of physical signs of severe, recurrent, or opportunistic infections. *Antineutrophil antibody* is enclosed in parentheses to indicate that the test has limited utility. *Abnl,* Abnormal; *AML,* acute myeloid leukemia; *ANC,* absolute neutrophil count; *CBC/diff,* complete blood count with differential count; *Dx,* diagnosis; *FH,* family history; *Hx,* history; *Ig,* immunoglobulin; *Q21 day,* every 21 days; *MDS,* myelodysplastic syndrome; *Nl,* normal; *Sx,* symptoms; *WHIM,* warts, hypogammaglobulinemia, infections, and myelokathexis.

associated immunoglobulin abnormalities. HIV testing is also indicated in chronic cases. Antineutrophil antibody testing, although technically imperfect (as discussed), is generally included in an initial evaluation because of the frequency of AIN.

Bone marrow aspiration and biopsy with cytogenetics should be part of the initial evaluation if leukoerythroblastosis, anemia, macrocytosis, or thrombocytopenia is present and should be performed eventually if the diagnosis remains obscure despite initial testing. If SCN is suspected, bone marrow analysis with cytogenetic screening for monosomy 7 should be performed both to establish the diagnosis (through demonstration of "maturation arrest") and to rule out MDS before G-CSF therapy. Other laboratory tests that should be considered, depending on the clinical situation, include evaluation for collagen vascular disease, exocrine pancreatic insufficiency, metabolic disorders (e.g. organic acidurias), and measurement of B_{12}, folate, and copper levels. Radiographic studies may be useful in the diagnosis of Shwachman-Diamond syndrome. Assessing the ANC before and 4 to 6 hours after a single dose of glucocorticosteroid (usually prednisone 1 to 2 mg/kg) measures mobilization of the bone marrow reserve pool of mature neutrophils[784,785]; an increase in the ANC to a normal or only moderately low level indicates "chronic benign" or idiopathic neutropenia and may render bone marrow examination unnecessary. The identification of genes responsible for most forms of congenital neutropenias (discussed previously) now permits specific genetic diagnosis in many cases and provides a basis for genetic counseling and prenatal diagnosis.

Principles of Therapy for Neutropenia

The management of neutropenia depends on the underlying cause and severity of the neutropenia.[574] The major concern in patients with neutropenia is the development of serious pyogenic infection. Patients with severe neutropenia (ANC ≤500 cells/μL) with poor marrow reserves are at highest risk for developing progressive infection and septicemia. Fever may often be the only indication of infection, because local signs and symptoms of inflammation may be diminished in the face of neutropenia. Organisms involved are usually from the skin or GI tract. Thus febrile patients with severe neutropenia caused by poor marrow function should be treated promptly with broad-spectrum antimicrobials after blood and other appropriate cultures are obtained, and treatment should be continued as long as the patient is febrile, even if blood cultures are negative. Patients with neutropenia who are febrile for more than 4 days while receiving broad spectrum antibacterial antibiotics are at risk for fungal infection, so empiric treatment with antifungal antibiotics should be considered in this setting.[786] Patients who have neutropenia with documented fungal infection or gram-negative bacterial sepsis who have not responded to appropriate therapy are candidates for granulocyte transfusions.[787-789]

Patients with neutropenia and normal to increased marrow cellularity (e.g., in the setting of AIN) often have a minimally increased risk of pyogenic infection and respond more briskly to appropriate antibiotics. A less aggressive course may be a reasonable approach to a febrile illness in such patients who appear clinically well, even if the ANC is below 500 cells/μL. A child with AIN who develops fever or infection can generally be managed as an outpatient unless the infection is severe.

Chronic gingivitis and periodontitis can be a persistent source of morbidity and result in tooth loss in patients with chronic or CyN. Good dental hygiene and regular professional treatment are necessary to forestall or prevent tooth loss and far outweigh any theoretical risk of bacteremia from local trauma.

The advent of recombinant G-CSF and other hematopoietic growth factors has revolutionized the therapy of neutropenias.[530,547,566,571,741,757] As discussed in previous sections, G-CSF has been successfully used to increase the neutrophil count in a wide variety of conditions including SCN, CyN, and immune-mediated neutropenias. Continuous G-CSF is recommended for all patients with SCN and other conditions with poor marrow production of neutrophils and a high risk of developing serious infection. For disorders with lower risks of infection, such as autoimmune or drug-induced neutropenia, G-CSF therapy should be reserved for specific clinical indications such as serious or repeated infections. In general, more frequent administration (daily or alternate days) of the lowest dose needed to achieve an ANC greater than 1000 cells/μL produces a more steady response and lower toxicity than less frequent administration (e.g., weekly) of higher doses. Polyethylene glycol-filgrastim has been used off label in a few patients who were unresponsive to filgrastim, but it causes considerable bone pain and more serious toxicities.[790,791]

Antibiotic prophylaxis, usually with trimethoprim-sulfa, may be useful for some patients with neutropenia and normal to increased myelopoiesis who do not meet criteria for G-CSF therapy.[757] There are no evidence-based data to indicate the effectiveness of measures beyond careful handwashing to prevent infections, most of which arise from the patients' own skin and gut flora; there is no need for reverse precautions or neutropenic diets in patients who have neutropenia without concurrent immunosuppression. To avoid invasive fungal infection, patients with chronic neutropenia should also avoid mulch, dusty construction or demolition sites, and bird or animal waste.[786,792]

Box 22-7 **Classification of Neutrophilia**

INCREASED PRODUCTION

- Chronic infection
- Chronic inflammation
  - Ulcerative colitis
  - Rheumatoid arthritis
- Tumors
- Postneutropenia rebound
- Myeloproliferative disease
- Drugs (lithium; rarely ranitidine, quinidine)
- Chronic idiopathic neutrophilia

ENHANCED RELEASE FROM MARROW STORAGE POOL

- Corticosteroids
- Stress
- Hypoxia
- Acute infection
- Endotoxin

REDUCED MARGINATION

- Stress
- Infection
- Exercise
- Epinephrine
- Leukocyte adhesion deficiency

DECREASED EGRESS FROM CIRCULATION

- Corticosteroids
- Splenectomy
- Leukocyte adhesion deficiency

Neutrophilia

Neutrophilia refers to an alteration in the total number of blood neutrophils that is in excess of about 7500 cells/μL in children and adults. During the first few days of life the upper limit of the normal neutrophil count ranges from 7000 to 13,000 cells/μL for neonates born prematurely and at term gestation, respectively,[793] and is followed by a decrease to adult levels within the first few weeks of life. An increase in circulating neutrophils is the result of a disturbance of the normal equilibrium involving neutrophil bone marrow production and movement in and out of the marrow and circulation. Three primary mechanisms accounting for neutrophilia[31,794] act most often in combination (Box 22-7). First, increased bone marrow production can expand the circulating neutrophil pool through: (1) increased progenitor cell proliferation and terminal differentiation through the neutrophilic series; (2) increased mitotic activity of neutrophilic cell precursors; or (3) shortening of the cell cycle time in the mitotic pool of neutrophil precursors. Second, increased numbers of neutrophils may be mobilized from either the bone marrow storage compartment or the peripheral marginating pools into the circulating pool. Additionally there may reduced neutrophil margination or egress into tissue.

Acute neutrophilia occurs rapidly within minutes in response to exercise or epinephrine-induced reactions and has been attributed to mobilization of the marginating pool of neutrophils into the circulating pool.[795,796] Slower onset of acute neutrophilia can occur after glucocorticoid administration or with inflammation or infection associated with the generation of endotoxin, TNF, IL-1, IL-8, and hematopoietic growth factors such as G-CSF.[6,7,785,797] Maximal response usually occurs within 4 to 24 hours after exposure to these agents and is probably the result of release of neutrophils from the marrow storage compartment into the circulation. The mechanisms that underlie release from the marrow pool involve interactions between neutrophils and the bone marrow stroma mediated by adhesion molecules (such as β2 integrins) and by chemokines such as CXCL12 and its receptor CXCR4.[40] Glucocorticoids may also slow the egress of neutrophils from the circulation into tissue.[798]

Chronic neutrophilia may accompany the prolonged administration of glucocorticoids, persistent inflammatory reactions, infection, chronic blood loss, or chronic anxiety.[799-803] Marked neutrophilia is a hallmark of functional disorders of neutrophils that are caused by impaired adhesion or motility, such as in patients with leukocyte adhesion deficiencies or actin dysfunction (see later). Sustained moderate neutrophilia invariably follows either surgical or functional asplenia,[804] probably because of decreased clearance of circulating neutrophils.[32] Neutrophilia also occurs in familial cold urticaria and periodic fever syndromes.[805,806]

Congenital primary neutrophilia is rare. In one family with AD hereditary neutrophilia, affected individuals maintained ANCs of 14,000 to 164,000 cells/μL along with hepatosplenomegaly, increased leukocyte alkaline phosphatase, and Gaucher-type bone marrow histiocytes.[807] A more recently-described AD neutrophilia kindred of 12 patients in three generations had an activating mutation in the *CSF3R* gene leading to constitutive activation of the G-CSF receptor and increased proliferation and differentiation of neutrophil precursors.[808] Affected family members had a median neutrophil count of 16,900 cells/μL (range: 11,000 to 23,700) and one progressed to MDS.

Leukemoid Reactions

Leukocyte counts greater than 50×10^3 normal cells/μL are referred to as *leukemoid reactions*.[809] The peripheral blood may show small proportions of immature myeloid cells, including occasional myeloblasts and promyelocytes. Leukemoid reactions need to be distinguished from chronic myelocytic leukemia (CML), which features a more extreme "left shift" and basophilia in the peripheral blood differential count, as well as the characteristic clinical, laboratory, and cytogenetics signs of a myeloproliferative disorder (see Chapter 11). Chronic neutrophilic leukemia is a distinct, extremely rare, malignant cause of mature neutrophilia, with a mean age at diagnosis of 62.5 years (range 15 to 86) in 33 reported cases.[810]

Leukemoid reactions are most commonly triggered by pyogenic infections, especially by *S. aureus* or *S. pneumoniae* but can also occur with other infections such as tuberculosis, brucellosis, or toxoplasmosis; with inflammatory syndromes such as acute glomerulonephritis or acute rheumatoid arthritis; and with liver failure or diabetic acidosis.[809,811] Infants with Down syndrome may develop a transient myeloproliferative disorder[812] (see Chapter 11) that is distinguishable by the marked leukoerythroblastosis with circulating blast cells. Leukemoid reactions have also been identified in neonates with thrombocytopenia-absent radius syndrome.[813]

Clinical States Associated with Alterations of Eosinophil Numbers

Eosinophilia

A very broad range of conditions can elicit an eosinophilic response (Box 22-8).[814] Eosinophil stimulation most commonly occurs after repetitive or prolonged antigen exposure, especially when the antigens are deposited in the tissues and elicit hypersensitivity reactions, whether of the immediate (IgE-mediated) or delayed (T-lymphocyte–mediated) type.[490] Stimulation of eosinophilia is T-lymphocyte–dependent and underlies the immune response to metazoan parasites.[14,490]

Allergy is the most common cause of eosinophilia in children in the United States.[815] Acute allergic reactions may cause leukemoid eosinophilic responses, with eosinophil counts exceeding 20,000 cells/μL, whereas chronic

Clonal hypereosinophilic syndrome (HES)
Idiopathic HES

allergy is rarely associated with eosinophil counts of more than 2000 cells/μL.[816] A variety of skin diseases have been associated with eosinophilia,[817] the best documented being atopic dermatitis, eczema, pemphigus, acute urticaria, and toxic epidermal necrolysis. Drug reactions often elicit eosinophilia,[818] including the potentially fatal drug rash with eosinophilia and systemic symptoms (DRESS) syndrome.[819]

Outside the United States, and hence also in immigrants and returning travelers, parasitic infections are the most common causes of eosinophilia.[820-822] Infestations by certain parasites, including helminths, induce greater degrees of eosinophilia than do protozoan infestations.[14,815,817] Other parasites such as *Giardia lamblia*, *Enterobius vermicularis,* and *Trichuris trichiura* fail to elicit an eosinophilic response, probably because they remain localized to the intestinal tract and do not enter somatic tissue.

When parasites invade systemic organs, they may incite clinical symptoms and signs related to the involved organs, such as hepatomegaly and pulmonary infiltrates. Complications include seizures, encephalitis, myocarditis, retinal lesions (that are often difficult to distinguish from retinoblastoma), and skin nodules on the palms of the hands and soles of the feet. Leukocyte counts may exceed 100,000 cells/μL, with marked eosinophilia persisting from months to years after resolution of symptoms. Polyclonal hypergammaglobulinemia is common. Increased anti-A and anti-B titers are commonly observed because of cross-reactivity between red cell and parasitic antigens.

Eosinophilia is also observed in scarlet fever, CMV pneumonia of infancy, cat-scratch disease, infectious lymphocytosis, and occasionally, infectious mononucleosis. Many patients with acute pulmonary tuberculosis show decreased numbers of circulating eosinophils followed by an increase in eosinophil numbers during the convalescent phase, but rarely patients exhibit marked eosinophilia at diagnosis.

In general, fungal diseases do not cause eosinophilia, but important exceptions are allergic and nonallergic fungal sinusitis and rhinosinusitis, coccidioidomycosis, and allergic bronchopulmonary aspergillosis.[817,823-825] The latter two diagnoses fit into the spectrum of pulmonary eosinophilic syndromes, which also include idiopathic eosinophilic pneumonia, Churg-Strauss syndrome (a form of vasculitis), tropical pulmonary eosinophilia (caused by microfilariae and other parasites), and drug- and radiation-induced pulmonary eosinophilia.[817,826,827]

GI disorders may also be associated with eosinophilia.[815,828] Primary eosinophil-mediated disorders usually involve the esophagus and stomach but can affect any or all segments of the GI tract.[828,829] Eosinophilia can also be a secondary sign of food allergy.[830] Inflammatory bowel disease and gluten enteropathy may involve large numbers of tissue eosinophils but show little or no elevation of blood eosinophil numbers.[831-833]

Eosinophilia is a prominent feature of several immunodeficiency disorders, especially hyper-IgE syndrome (HIES; Job syndrome) (see later), Wiskott-Aldrich and Omenn syndromes,[834,835] and hereditary angioedema.[836,837] Approximately 10% of patients with rheumatoid arthritis develop mild eosinophilia during the course of their disease.

AD familial eosinophilia has been reported in several families in which individuals displayed marked eosinophilia, but few had pulmonary, cardiac, or neurologic involvement.[838,839] The disorder has been mapped to chromosome 5q31-q33, a region that contains a cytokine cluster including genes encoding IL-3, IL-5, and GM-CSF.[840] However, no mutations or functional polymorphisms have been identified within the promoter, exons, or introns of any of these genes, suggesting that the primary defect in familial eosinophilia is located in another gene in the cluster. The disorder can be distinguished from HES (see the following section) by the relative absence of eosinophil activation markers and rarity of end organ damage.[839]

Marked eosinophilia can accompany or precede the diagnosis of malignancies including Hodgkin and non-Hodgkin lymphomas, acute lymphoblastic leukemia, and a variety of solid tumors.[817,841,842] Excessive numbers of normal eosinophils may also be produced in response to production of cytokines, primarily IL-5, by abnormal (but only sometimes clonal) T cells with aberrant immunophenotypic markers.[843] About one third of patients undergoing chronic hemodialysis develop blood eosinophilia without an apparent cause.[844] Similarly, chronic peritoneal dialysis may cause an eosinophilic peritoneal effusion and occasionally an elevated number of eosinophils in the blood.[845]

Eosinophilia can produce organ damage, particularly to the heart, lungs, and GI tract, by infiltration and deposition of toxic granule proteins. If treatment of the underlying infection or disease is not sufficient to reduce the eosinophil count, then steroid therapy generally produces a rapid decline in eosinophil production and circulating cell numbers. Steroid-sparing targeted therapies such as monoclonal antibodies directed at IL-5 or IL-5R (e.g., mepolizumab, reslizumab, and benralizumab) or at T cells (e.g., alemtuzumab) have shown efficacy, and a variety of additional biologic agents are in development.[846]

Hypereosinophilic Syndrome

HES is defined as a persistent eosinophilia in patients that meet the following criteria: (1) absolute eosinophil count of 1500 cells/μL or more for longer than 6 months (or fatal termination within 6 months); (2) lack of other diagnoses to explain secondary eosinophilia; and (3) signs and symptoms of organ involvement by infiltrating eosinophils.[847,848] Clinical manifestations result from tissue infiltration by eosinophils and the release of eosinophil granule products that cause tissue damage. Symptoms include nonspecific findings of fever, weight loss, and fatigue. Cardiac damage is the major cause of morbidity and mortality in HES and includes endocardial fibrosis and formation of mural thrombi with infiltrating eosinophils (Loeffler endocarditis).[815,817,849] These findings can also be seen from eosinophilia of multiple other etiologies, including parasitic infection, drug reactions, or secondary to malignancies. Hepatosplenomegaly, pulmonary infiltrates, and skin involvement with urticarial or nodular lesions are common; neuropathies, encephalopathy, and CNS thromboembolism can also occur.

The recognition of specific gene rearrangements has provided a molecular basis for understanding the pathophysiology, developing classification systems, and guiding treatment.[846,848,850-853] The most common involve the gene encoding the platelet-derived growth factor receptor α, *PDGFRA*, which forms fusion products that generate constitutively active tyrosine kinase molecules.[854,855] The most common fusion partner is the Fip1-like 1 gene, *FIP1L1*, resulting from an interstitial chromosome 4q12 deletion that is not cytogenetically detectable; however, multiple rarer fusions and cytogenetic changes have been reported.[851] These rearrangements result in HES with a marked male predominance and a phenotype that includes splenomegaly, elevated serum vitamin B_{12} and tryptase levels, and hypercellular bone marrow with fibrosis and increased eosinophils and mast cells. Other patients with clonal HES have a wide variety of rearrangements involving the *PDGFRB* gene, which encodes platelet-derived growth factor receptor β, and rare cases have been reported with rearrangements of *FGFR1*, which encodes fibroblast growth factor receptor 1, and other genes.[851] Importantly, patients with PDGFR fusion products are likely to respond to imatinib therapy, sometimes at dosages lower than those used for CML.[846,850]

There is still no consensus on classification of HES, in part because of overlap between primary and secondary hypereosinophilia.[814,848,851,853] The most general classification groups the syndromes as: (1) primary neoplastic HES with an underlying clonal abnormality; (2) secondary HES caused by an underlying neoplastic or nonneoplastic condition leading to nonclonal eosinophilia; and (3) idiopathic HES. The diagnosis of chronic eosinophilic leukemia is very difficult to distinguish from clonal HES, although the World Health Organization classification makes this distinction.[848] The lymphoid form of secondary HES is a distinct variant caused by monoclonal expansion of T cells with an indolent course and rare evolution to T-cell lymphoma.[490]

HES can generally be distinguished from the M4Eo variant of AML, which is characterized by myelomonocytic blasts with eosinophilia and inv(16) cytogenetics (see Chapter 11).

Eosinopenia

Eosinopenia is not uncommon but is seldom recognized clinically, because its precise diagnosis requires an absolute eosinophil count.[856] Eosinopenia may be produced by at least two mechanisms: (1) primary elevation of adrenal corticosteroids or epinephrine; and (2) acute inflammation or stress, acting in part through secondary release of adrenal corticoids and/or epinephrine. The immediate eosinopenia after administration of glucocorticoids reflects the destabilization of mRNA encoding cytokines such as eotaxins and inhibition of the cytokine-dependent survival of eosinophils.[14,857] Glucocorticoids also suppress the transcription of a number of genes involved in eosinophil production and trafficking, including IL-3, IL-4, IL-5, and GM-CSF.[14] Acute inflammation is associated with alterations in eosinophil distribution and production; at least part of this response occurs independently of adrenal corticoid release.

Box 22-9 Disorders Associated with Basophilia

MILD BASOPHILIA

- Hypersensitivity reactions
  - Drug and food hypersensitivity
  - Urticaria
- Infection
  - Helminths
  - Chickenpox
  - Influenza
  - Smallpox
  - Tuberculosis
- Inflammation
  - Rheumatoid arthritis
  - Ulcerative colitis
- Hypothyroidism (severe)

MARKED BASOPHILIA

- Chronic myelogenous leukemia
- Myelodysplastic syndrome
- Acute myeloid leukemia (rare)

Basophilia and Basophilopenia

Basophils are associated not only with hypersensitivity reactions of the immediate type but also have increasingly recognized roles in innate immunity, particularly to helminthes and other parasites.[150,858-860] Basophil levels may be elevated in allergic responses; infections with helminthes, viruses, and mycobacteria; and chronic inflammatory diseases (Box 22-9).[157,861,862] Most importantly, basophil levels are increased in myeloproliferative disorders such as CML (see Chapter 11). Basophil counts exceeding 30% can occur during the course of CML; marked basophilia often heralds a poor prognosis,[863,864] and the cells may be morphologically and functionally abnormal.[865,866] Patients with marked basophilia may develop symptoms attributed to the release of biogenic amines or heparinlike material released from degranulated basophils[866] and may benefit from the administration of antihistamines. Increased numbers of marrow basophils may occur in MDS and sideroblastic anemia.[867,868] Peripheral blood or bone marrow basophilia may also accompany acute myeloid leukemias, usually in association with 6p or 12p chromosomal abnormalities,[869] or juvenile myelomonocytic leukemia.[866]

Basophilopenia occurs in conditions that are associated with eosinophilopenia, such as during acute infection or after the administration of glucocorticoids.[870-872] Basophil counts are diminished in thyrotoxicosis and after treatment with thyroid hormones, and conversely they may be increased in myxedema.[870]

Monocytosis and Monocytopenia

The normal absolute blood monocyte count varies with the age of the patient, and this variation must be taken into account when assessing monocytosis. During the first 2 weeks of life, the absolute monocyte count is more than 1000 cells/μL.[873] With increasing age, there is a gradual

Box 22-10 Disorders Associated with Monocytosis

INFECTION

Subacute bacterial endocarditis
Tuberculosis
Syphilis
Protozoal and rickettsial infections (e.g., Rocky Mountain spotted fever, kala-azar)

MALIGNANCY

Recovery from transient neutropenia
Postsplenectomy status
Alcoholic liver disease
Tetrachloroethane poisoning

decline in the monocyte count until it reaches a plateau of 400 cells/μL in adulthood. Monocytosis may therefore be defined as a total monocyte count of more than 500 cells/μL. Many clinical disorders give rise to monocytosis (Box 22-10), most typically bacterial, protozoan, and rickettsial infections such as subacute bacterial endocarditis, tuberculosis, syphilis, Rocky Mountain spotted fever, and kala-azar.[167] Monocytosis is a hallmark of juvenile myelomonocytic leukemia (see Chapter 11) and can also be observed in malignant disorders such as preleukemia, AML, CML, lymphomas, and advanced stage carcinomas.[874] Approximately 25% of all patients with Hodgkin lymphoma have monocytosis, which does not correlate with prognosis.[875] Monocytosis has also been noted in a wide variety of inflammatory and immune disorders including lupus, rheumatoid arthritis, sarcoidosis, and inflammatory bowel disease.[876] Finally, as discussed, both relative and absolute monocytosis occurs in some forms of severe chronic neutropenia and in patients recovering from myelosuppressive chemotherapy.

Monocytopenia has been observed after glucocorticoid administration and in infections associated with endotoxemia.[877,878] In the latter case, systemic activation of complement occurs with the deposition of C5a on the surface of monocytes, leading to their aggregation and clearance. Decreased monocyte superoxide production, chemotaxis, and microbial killing have been reported in Gaucher disease, possibly contributing to the risk of infections in this disease.[879-881] The defects are reversed at least partially by enzyme replacement therapy.[879]

Monocytopenia is a primary feature of the recently described MonoMAC syndrome. This pleiotropic disorder also includes, to varying degrees, B- and NK-cell deficiencies; mild neutropenia; susceptibility to severe and chronic nontuberculous mycobacterial, fungal, and viral infections; predisposition to MDS, myeloid leukemias, and autoimmunity; pulmonary alveolar proteinosis; and lymphedema.[649,882-886] Deficient NK-cell function reflects the selective loss of CD56 bright cells.[887] The syndrome includes phenotypes previously reported as Emberger syndrome (AD deafness, lymphedema, and MDS/AML)[888,889] and NK-cell deficiency with severe herpes virus infections.[890] MonoMAC syndrome derives from hypomorphic and regulatory mutations that diminish expression of the GATA-2 transcription factor,[891,892] which regulates development and function in multilineage hematopoiesis and lymphangiogenesis, as well as leukemogenesis.[886,893] The disorder has been treated successfully by HSCT.[894]

Monocytopenia is a feature of another immunological disorder, so far unnamed, that is caused by mutations in the *IRF8* gene and resulting in monocytopenia, absent or deficient dendritic cells, and immunodeficiency presenting as disseminated bacille Calmette-Guérin (BCG) disease.[895]

Infantile (malignant) osteopetrosis is a hereditary disease of bone marrow replacement by bone that is caused by a failure of bone resorption and remodeling by osteoclasts, a form of specialized tissue macrophage.[212,896,897] This disorder presents in infancy and is characterized by the progressive obliteration of the bone marrow space by bone, leading to progressive loss of marrow function, hepatosplenomegaly, growth retardation, and compression of cranial nerves.[212] AR and less severe AD osteopetrosis are caused by mutations in any of multiple genes involved in receptor activator of nuclear factor κB and its ligand (RANK and RANKL) signaling, receptor-mediated endocytosis, vacuolar proton and chloride transport, G-protein degradation, or vesicular sorting.[217,218,898-904]

Generation of superoxide by peripheral blood leukocytes is defective in some patients with AR (malignant) osteopetrosis[905] and recombinant IFN-γ (also used for CGD; see later) has been shown to increase bone resorption and improve hematopoietic marrow function in children with infantile osteopetrosis.[906] Infantile osteopetrosis is generally treated with bone marrow transplantation,[212,907] Promising studies in mouse models suggest that RANKL administration or gene therapy might provide future therapeutic options.[908,909]

DISORDERS OF GRANULOCYTE AND MONONUCLEAR PHAGOCYTE FUNCTION

Abnormalities in one or more steps of phagocyte function—adhesion, chemotaxis, ingestion, degranulation, and oxidative metabolism—are causes of inherited and acquired clinical disorders that can be classified based on the function primarily affected. Consistent with the critical role of phagocyte function in host defense, patients afflicted with these disorders often suffer from recurrent, difficult-to-treat bacterial and fungal infections in skin or mucosa, lung, lymph nodes, or deep-tissue abscesses. Many of these disorders have characteristic clinical and microbiologic features related to the particular functional defect. Finally, inherited disorders involving cytokine or TLRs and their signal transduction are increasingly recognized, many of which affect phagocyte function and result in recurrent infections. These are described near the end of this chapter.

Of note, in clinical practice most physicians encounter a number of patients who suffer from recurrent bacterial infections. Whereas it is true that nearly all patients with well-characterized phagocyte abnormalities have recurrent infections, the converse is seldom the case. Most patients with impressive histories of persistent and repeated infections do not have identifiable qualitative or quantitative phagocyte abnormalities.[910] Therefore the disorders described below account for only a fraction of patients with recurrent infections. This point will be discussed further in the final section describing the laboratory evaluation of phagocyte function.

Disorders of Adhesion

Leukocyte Adhesion Deficiency Type I

LAD I is a rare AR disorder in which phagocyte adhesion, chemotaxis, and ingestion of C3bi-opsonized microbes is impaired because of mutations in the gene for the β subunit of the β_2 integrins, CD18. As a result, the expression of β_2 integrins on leukocyte cell surfaces is reduced or absent.[274,911-914] More than 100 patients with this disorder have been described in the literature. The hallmark of LAD I is the occurrence of repeated, often severe bacterial and fungal infections without the accumulation of pus despite a persistent granulocytosis (Table 22-10). The clinical syndrome is heterogenous and is related to the severity of the reduction in β_2-integrin expression. Most patients have a severe clinical phenotype, in which fewer than 0.3% of the normal amount of β_2 integrins are present, although a more moderate phenotype with levels of 2.5% to 11% of normal has been observed. Patients with the severe form of LAD I generally show signs in early infancy with neutrophilia, omphalitis, and delayed separation of the umbilical cord. Recurrent necrotic and indolent infections of skin, mucous membranes, and the GI tract are also seen, including perirectal abscesses, which often heal poorly. An aggressive form of gingivitis and periodontitis is characteristic, and ulcerative lesions of the tongue and pharynx can be seen. Otitis media and pneumonia are also often encountered. Most infections are caused by *S. aureus* and gram-negative enteric bacteria. Fungal infections also occur, particularly *Candida albicans* and *Aspergillus* species.

The molecular basis for LAD I was first suggested by Crowley and colleagues,[915] who found that neutrophils from a patient with this clinical syndrome lacked a high–molecular-weight membrane glycoprotein. Because the patient's neutrophils neither adhered to plastic surfaces nor underwent an oxidative burst when exposed to serum-opsonized particles, it was hypothesized that the missing glycoprotein was responsible for both adhesion and cell-particle interactions. A similar glycoprotein was also found to be missing in several other patients,[916,917] and that proved to be the α subunit (CD11b) of the Mac-1 β_2 integrin (CD11b/CD18).[918] It was subsequently recognized that the levels of all leukocyte β_2 integrins (see Fig. 22-5) were absent or severely deficient in LAD I.[911]

Deficient β_2-integrin expression impairs a variety of leukocyte adhesion-dependent activities, with neutrophils being the most significantly affected.[274,911,912,914-916] In addition to their role in mediating adhesive interactions during neutrophil emigration and phagocytosis, signaling through β_2 integrins potentiates virtually all functional responses of adherent neutrophils, including production of reactive oxidants and degranulation.[919] Hence LAD I neutrophils have a profound defect in their ability to become fully activated.

A striking finding in LAD I is the failure of neutrophils to migrate to sites of inflammation. The initial phases of neutrophil adhesion to the endothelium (see Fig. 22-3), which is mediated by selectins and their sialylated counter receptors, is normal in LAD. However, because of deficient Mac-1 (CD11b/CD18) expression, LAD I neutrophils are neither able to attach firmly to the endothelium

TABLE 22-10 Clinical Features of Leukocyte Adhesion Deficiency Type I

*Each list is arranged in approximate order of incidence based on reviews summarizing various series of patients with leukocyte adhesion deficiency.

nor undergo transendothelial migration.[920] Neutrophil intravascular survival is prolonged,[921] presumably related to deficient adhesion and migration. In vitro assays of neutrophil adhesion to glass or to cultured endothelial cells and of neutrophil chemotaxis also exhibit marked abnormalities. An exception to these observations is neutrophil adhesion and emigration in the pulmonary capillary bed, which can be mediated by CD11/CD18-independent mechanisms.[289] In autopsy tissue from a patient with severe LAD I, no neutrophils were observed in infected appendiceal and skin lesions, whereas many neutrophils were seen within the alveolar spaces.[289] In contrast to neutrophils, other leukocytes (monocytes, eosinophils, and lymphocytes) express the β_1 integrin, VLA-4 and are able to utilize this adhesion molecule to emigrate into inflammatory sites throughout the body.

Another major defect in LAD I is the inability of neutrophils and monocytes to recognize microorganisms coated with the opsonic complement fragment C3bi, since Mac-1 is a major C3bi receptor.[911,915,922] The binding of C3bi normally triggers neutrophil degranulation, phagocytosis, and activation of the respiratory burst, but these responses are diminished or absent in neutrophils from patients with LAD I. However, these responses can be at least partially activated in LAD I neutrophils by opsonins (e.g., IgG, C3b) that have different cell surface receptors or by soluble agonists that bypass Mac-1.[915,919]

Defects in LAD I lymphocyte functions dependent on LFA-1 (CD11a/CD18) are often reported when assayed in vitro. These include proliferative responses to mitogens, NK-cell function, and lymphocyte-mediated killing.[923-925] Nevertheless most patients with LAD I manifest few if any problems related to lymphocyte dysfunction in vivo. Cutaneous hypersensitivity reactions are normal, and patients are generally not unusually susceptible to viral infections, including varicella. However, one patient has died of an overwhelming respiratory infection with picornavirus, and one or more episodes of aseptic meningitis have been reported in three patients.[926]

Molecular Basis of Leukocyte Adhesion Deficiency. That LAD I involves a deficiency of all leukocyte β_2 integrins focused attention on the common β_2 chain (CD18) of this integrin family as the site of the molecular defect. This hypothesis proved to be correct. Expression of the leukocyte-integrin α subunits is normal in LAD I, but these are not transported to the cell surface because the β_2 chain is absent or contains mutations that disrupt β_2 structure or its interaction with the α subunit.[927,928] More than 80 different LAD I-associated mutations in the β_2 gene *IBTG2*, located on chromosome 21q22.3, are reported.[929] A database is available at http://bioint.uta.fi.[930] Many patients are compound heterozygotes for two different mutant alleles, whereas others are homozygous for a single mutant allele. About one half of patients with LAD I and characterized genetic defects have point mutations that result in single amino-acid substitutions in CD18 that almost invariably reside between amino acids 111 and 361 encompassed by exons 5 to 9.[929] This protein domain is highly conserved among all β subunits, and appears to be important for interaction with the α subunit. In this LAD I subgroup, approximately one half exhibit a low level of CD11/CD18 cell-surface expression and moderate disease, with the remainder having absent expression and the severe phenotype. Other LAD I-associated mutations include mRNA-splicing defects as well as small deletions within CD18 coding sequences, resulting in a premature termination signal. Mutations resulting in nonfunctional but normally expressed β_2 occur, but very rarely.[929]

There are several animal models of LAD I.[912] These include the occurrence of a severe form of the disease in an Irish setter born of a mother-son mating[931,932] and in Holstein cattle.[933,934] In the latter case, affected calves could be traced to a common sire and were homozygous for a point amino-acid substitution in the conserved extracellular domain of CD18.[935] Finally, CD18-deficient mice have produced by gene targeting.[912]

Diagnosis and Treatment of LAD I. The diagnosis of LAD I should be suspected in any infant or child who has unusually severe or recurrent infections and/or periodontitis accompanied by persistently elevated peripheral blood neutrophil counts, particularly if there is a paucity of neutrophils at affected sites and/or there is a delayed separation of the umbilical cord (see Table 22-10). However, a well infant with delayed separation of the umbilical cord and normal blood counts is very unlikely to have LAD I. Although the mean age of cord separation is reported to be 7 to 15 days, 10% of healthy infants can have cord separation at 3 weeks of age or later.[936,937] A rare cause of recurrent, deep-seated tissue infections in association with neutrophilia and poor formation of pus is mutation of the Rac2 GTPase, which leads to neutrophil signaling defects affecting chemotaxis and adhesion (see "Disorders of Chemotaxis").[97-99,938]

The diagnosis of LAD I is established by flow cytometry to assess cell surface expression of any of the β_2-integrin α (CD11) subunits or the shared CD18 subunit (Fig. 22-14). Neutrophil Mac-1 deficiency is more dramatic if neutrophils are first stimulated, which normally upregulates Mac-1 cell-surface expression. Carriers of LAD I can generally be identified by flow cytometry, because they typically express approximately 50% of the normal level of β_2 integrins on leukocyte cell surfaces.[911,939] Commercial genetic testing is also available.

Treatment of LAD I depends on the clinical severity of the disorder. In patients with the moderate clinical phenotype, who typically have residual β_2-integrin expression, cutaneous and oral infections should be treated aggressively. The use of prophylactic trimethoprim/sulfamethoxazole appears to be beneficial. Aggressive prophylactic treatment of periodontal disease is also advisable in the form of frequent dental cleanings and the use of antimicrobial oral rinses such as chlorhexidine. The clinical management of patients with moderate phenotype should be guided by the observation that these patients are still at risk for dying of overwhelming infection.[274,914] Patients with severe LAD I have even a more grim prognosis, with a high incidence of death from infection before the age of 2 years, and therefore bone marrow

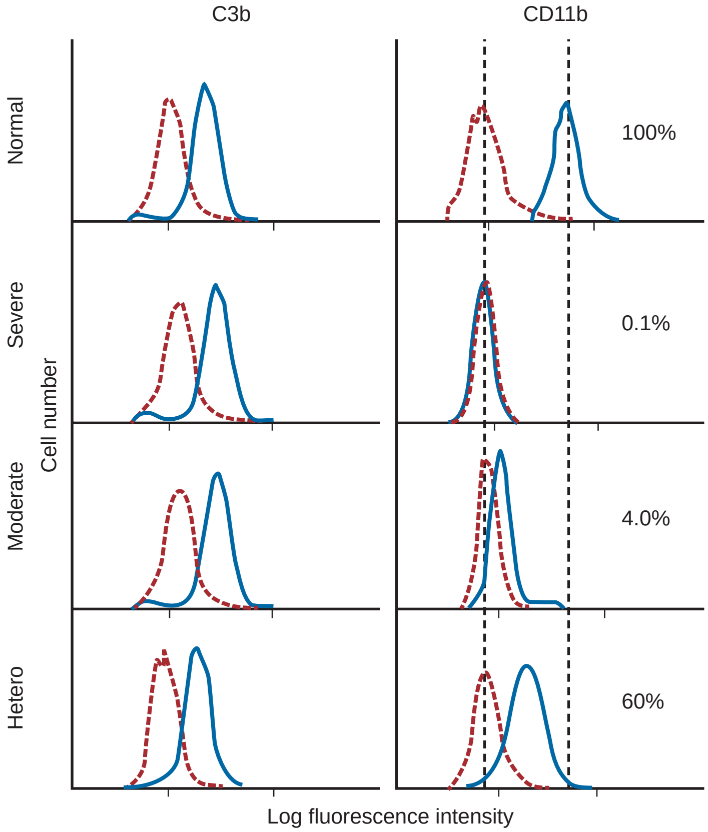

Figure 22-14 Evaluation of adhesion molecule expression for diagnosis of leukocyte adhesion deficiency (LAD). Fluorescence of C3b specific antibody labeled neutrophils *(solid line)* increases compared with a nonspecific control *(dashed line)* after 30-minute exposure to 10-nM fMLP in healthy donors, subjects with severe and moderate forms of LAD I, and a heterozygous LAD I carrier. However, the increase in CD11b fluorescence *(solid line)* is markedly diminished in patients with LAD 1. The respective percentage of normal stimulated mean channel number is shown in the *right column*. Note that these results are expressed as percentage of normal fluorescence intensity, not as a percentage of positive cells, as is the case in most flow cytometry assays. *(Modified from Dinauer MC, Coates TD: Disorders of phagocyte function. In Hoffman R et al, editors:* Hematology: basic principles and practice, *6th ed. Philadelphia, 2012, Saunders, p. 667.)*

transplantation is recommended.[274,914,940] A recent study reported 75% survival in LAD I patients after allogeneic transplantation using either ablative or reduced intensity regimens.[941] Graft rejection or graft-versus-host disease can be problematic with partially compatible human leukocyte antigen (HLA) matching.[941,942]

Gene therapy to correct CD18 expression in a patient's HSCs may be a future therapeutic modality. High-level expression of the transferred CD18 sequence may not be necessary to confer substantial clinical benefits, based on the observed milder course of patients with residual β_2-integrin expression. Studies in canine LAD I suggest that restoring CD18 expression to even 10% of leukocytes will result in clinical improvement,[940,943] and current preclinical efforts are focused on the development of lentivirus or foamy virus vectors to express a normal CD18 gene.[944,945] Obstacles for clinical translation have been the development of techniques that achieve high-level gene transfer into human HSCs and minimizing adverse effects of vector insertion.[940,946,947]

Leukocyte Adhesion Deficiency Type II

LAD II is a very rare AR clinical syndrome similar to LAD I but associated with defective selectin-mediated adhesion resulting from deficiency of Sialyl-Lewis X ligands (Table 22-11).[913,948-952] First described by Etzioni and colleagues,[948] it has since been described in a total of 5 kindreds (4 Arab and 1 Turkish). As in CD11/CD18-deficient LAD, these children suffered from periodontitis, recurrent cellulitis, otitis media, and pneumonia without the formation of pus despite peripheral leukocyte counts of 30,000 to 150,000 cells/μL. However, neutrophils had normal levels of CD18, and infectious symptoms were not as serious as in LAD I. Also in distinction from classic LAD I, the affected children had short stature, a distinctive facial appearance with a flat face and depressed nasal bridge, and severe mental retardation. All had the rare Bombay (hh) blood phenotype, a clue to the molecular defect in which red cells express a nonfucosylated variant of the H antigen. Red cells were also were secretor negative and Lewis antigen negative. The Bombay and nonsecretor phenotypes are caused by deficient formation of Fucα1 to 2 Gal linkages in ABO blood group core antigens, whereas the Lewis antigen-negative phenotype is the result of failure to synthesize Fucα1 to 4 GlcNAc and Fucα1 to 3 GlcNAc moieties.

The defect in fucose metabolism in LAD II cells results from point mutations in the *SLC35C1* gene encoding the

TABLE 22-11 Types of Leukocyte Adhesion Deficiency

	Genetic Defect	Clinical Presentation	Diagnosis
LAD I	CD18 (β_2) subunit of β_2 integrins, resulting in impaired adhesion, chemotaxis, and neutrophil activation	Skin infection, soft tissue abscesses, delayed separation of umbilical cord and omphalitis, periodontal disease	Flow cytometry for leukocyte β_2 integrins
LAD II	GDP-fucose transporter 1, resulting in impaired expression of fucosylated proteins, including SLeX ligand for selectins	Similar infections to LAD I but not as severe; developmental delay, short stature	Flow cytometry for leukocyte CD15s (SLeX) Bombay (hh) phenotype in red blood cell typing
LAD III	Kindlin 3, a regulator of β integrins in blood cells, resulting in defective integrin activation and impaired leukocyte and platelet adhesion	Similar to LAD I; also bleeding tendency	Functional assays for neutrophil and platelet adhesion

GDP, Guanosine diphosphate; *LAD,* leukocyte adhesion deficiency.

Golgi GDP-fucose transporter 1.[951,952] This leads to a generalized loss of fucosylated glycans on cell surfaces, particularly the sialylated and fucosylated tetrasaccharide, SleX (CD15a) on the neutrophil. As a result, LAD II neutrophils cannot bind to E- and P-selectin receptors. The early step of neutrophil rolling on activated endothelial cells is defective in LAD II,[920,948] consistent with the role of selectin-mediated adhesion in this process (see Fig. 22-3). However, chemoattractant-induced tight adhesion and emigration of LAD II neutrophils is normal, both of which are severely impaired in LAD I.[920] Several *slc35c1*-deficient mouse models are available.[274]

All of the Arab patients have the same nucleotide substitution in the Golgi GDP-fucose transporter mRNA, which alters an amino acid in a transmembrane domain, whereas the Turkish patient has a different nucleotide alteration that results in an amino acid substitution in a different transmembrane domain of the transporter.[951,952] The different mutations may explain why the Turkish patient had some response to oral fucose therapy with increased expression of certain fucosylated ligands and improved clinical symptoms except mental retardation, but the Arab children did not.[949,953] It is speculated that the mutation in the Turkish child leads to a decrease in transport affinity for GDP fucose, which can be overcome by higher concentrations of fucose, whereas the mutant protein in Arab children has normal affinity for GDP fucose but decreased transport activity.[950]

Leukocyte Adhesion Deficiency Type III

LAD III is the most recently described subgroup of LAD and is characterized by both severe, recurrent infections and leukocytosis similar to LAD I as well as a severe bleeding tendency similar to Glanzmann thrombasthenia, a β_3-related disorder (see Table 22-11).[954-958] First described in 1997 by Kuijpers and colleagues and originally named LAD-1/variant syndrome, almost a dozen patients have now been reported in the literature, many of whom are descendants of Turkish ancestors.[274,914,954-960]

In contrast to LAD I, integrin expression in LAD III patients is normal or near normal. Instead there is a defect in the inside-out activation of hematopoietic cell integrins to a high-affinity binding state. Gene targeted mice lacking Kindlin 3, a blood cell-specific cytoplasmic protein that cooperates with talin to activate β_1, β_2, and β_3 integrins had a similar phenotype to these patients,[274] leading to the discovery of mutations in the *FERMT3* gene and absence of its Kindlin 3 protein product in patients with LAD III.[280,282,284,961] Additional mutations in a blood cell-specific guanine nucleotide exchange factor, CalDAG-GEFI, were originally implicated as causing LAD III in several Turkish kindreds.[960,962] However, these patients also had mutations in *FERMT3,* and gene rescue experiments showed that restoring Kindlin 3 expression corrects the defects in integrin-mediated adhesion and migration.

As mentioned, patients with LAD III have severe, recurrent infections as well as a bleeding diathesis that can be variable in severity. Kindlin 3 is also reported present in erythrocytes, similar to mice, and its loss is proposed to contribute to anemia and poikilocytosis in some patients with LAD III.[963] Because of defects in osteoclast integrin activation, Kindlin 3–/– mice have osteopetrosis, as do some patients who have LAD III.[274] The diagnosis of LAD III should be considered in patients with the clinical features of LAD I but normal expression of β_2 integrins and, commonly, bleeding with abnormal platelet aggregation. Commercial genetic testing is available. Supportive care includes prophylactic antibiotics and transfusion, as needed. However, because the clinical manifestations are typically severe, early bone marrow transplantation may be indicated.[274,954,958,964]

Acquired Disorders of Adherence

Neutrophils may exhibit decreased adhesiveness after exposure to a variety of drugs, the most common being corticosteroids and epinephrine.[796,965,966] Clinically the diminished adhesiveness induced by these drugs is manifested by a dramatic rise in the total neutrophil count in the blood as cells from the marginated pool are quickly released into the circulating pool. Whereas the mechanisms by which corticosteroids alter adherence are likely complex,[967] epinephrine and other β-adrenergic agonists exert their effect indirectly by causing endothelial cells to release cyclic adenosine monophosphate (cAMP), which in turn impairs the ability of neutrophils to adhere.[796,968]

The adhesiveness in neutrophils can be dramatically increased in a variety of clinical conditions that have in common the formation of biologically active complement fragments: gram-negative bacterial sepsis, severe thermal injury, pancreatitis, trauma, and exposure of neutrophils to artificial membrane surfaces during hemodialysis and cardiopulmonary bypass.[969] In these various conditions, the generation of complement fragments leads to activation of neutrophils and enhanced adhesiveness, possibly owing to enhanced expression of β_2 integrins. Under these conditions, neutrophils undergo increased aggregation with each other and become trapped within capillary beds, such as those in the lungs.[970] It is believed that the aggregated neutrophils then generate toxic oxygen radicals and release proteases that conspire to damage structural protein such as collagen and elastin.[305] Binding of viral proteins to neutrophils can depress adhesion and other neutrophil functions in influenza or HIV infection.[969]

Amphotericin B has been associated with increased neutrophil aggregation, particularly when administered in conjunction with transfusions of neutrophils that have been harvested by filtration (rather than by centrifugation).[971,972] It is possible that the enhanced aggregation is mediated by upregulation of surface β_2 integrins induced both by the amphotericin B and by the filters used to harvest the cells. Liposomal amphotericin causes substantially less in vitro aggregation of mobilized neutrophils and therefore may be easier to use in patients being treated for fungal infections who are also receiving allogeneic neutrophil transfusions.[973]

Disorders of Chemotaxis

The directed migration into sites of infection and inflammation involves a complex series of events. As reviewed in the beginning of this chapter, the generation of chemotactic signals and their binding to specific surface receptors activate leukocyte intracellular signaling pathways that trigger changes in adhesiveness and in the actin cytoskeleton leading to binding to the endothelium and chemotaxis into inflamed tissue. Given the numerous cellular functions involved in chemotaxis, it is perhaps not surprising that impaired phagocyte chemotaxis is observed in a large number of clinical conditions.[969,974] Some of the more important syndromes are listed in Box 22-11. These disorders are classified according to the mechanisms thought to be responsible for defective chemotaxis. In some cases, abnormal chemotaxis is one component of a disorder that involves multiple defects.

It is worth noting that in many of the reports describing defective in vitro chemotaxis of neutrophils from various clinical conditions, it is not clear whether an increased number of infections is a result of the observed chemotactic abnormality or of medical complications of the underlying disorder. Further complicating the interpretation of these reports is that the in vitro assays for chemotaxis are subject to laboratory artifacts and may not accurately reflect the in vivo extracellular environment.[975-977] Although now rarely used in practice, phagocyte migration to an inflamed site in vivo can be measured by the skin window technique of Rebuck and Crowley, in which a superficial dermal abrasion is produced,[978] or in skin blisters induced by suction,[979] and the appearance of inflammatory cells in the lesion are monitored over 24 hours.

Box 22-11 **Clinical Conditions Associated with Impaired Neutrophil Chemotaxis**

DEFECT IN GENERATION OF CHEMOTACTIC AGENTS

Familial deficiency of C1r, C2, C4
Familial deficiency of C3, C5
Other abnormalities of complement pathways (e.g., systemic lupus erythematosus, immature complement system in neonates, diabetes mellitus, C5 dysfunction, chronic hemodialysis, glomerulonephritis)

EXCESSIVE PRODUCTION OF NORMAL CHEMOTACTIC FACTOR INACTIVATORS

Hodgkin disease
Cirrhosis of the liver
Sarcoidosis
Lepromatous leprosy

INHIBITORS OF THE NEUTROPHIL RESPONSE TO CHEMOTACTIC FACTORS

Hyperimmunoglobulin E syndrome
Localized aggressive periodontitis (LPA)
Immune complex diseases (rheumatoid arthritis, systemic lupus erythematosus)
Influenza virus
Human immunodeficiency virus
Immunoglobulin A paraproteinemia states
Solid tumors
Bone marrow transplantation
Drugs (ethanol, antithymocyte globulin, interleukin-2)

DEACTIVATION (DOWNREGULATION) BY INCREASED LEVELS OF CHEMOTACTIC FACTORS

Wiskott-Aldrich syndrome
C5a generation in plasma (hemodialysis)
Bacterial sepsis

PHAGOCYTE DEFECTS

Neutrophil actin dysfunction
Rac2 mutation
LAP
Neonatal neutrophils
Leukocyte adhesion deficiency
Chédiak-Higashi syndrome
Specific granule deficiency
Glycogen storage disease 1b

MISCELLANEOUS DEFECTS

Hypophosphatemia
Shwachman-Diamond syndrome
Burn patients

As outlined in Box 22-11, several of the conditions associated with impaired neutrophil chemotaxis are caused by complement deficiencies and other immunodeficiency syndromes (e.g., WAS). These disorders are discussed elsewhere in this text. In addition, several disorders of phagocyte function (LAD, CHS, and SGD) are reviewed in other sections of this chapter. The following section focuses on well-defined clinical entities in which impaired chemotaxis is the predominant feature of phagocyte dysfunction and contributes to increased risk of infection.

Hyperimmunoglobulin E Syndrome

HIES (see Chapter 24) is a complex multisystem disorder characterized by markedly elevated serum levels of IgE

Box 22-12 Summary of Hyperimmunoglobulin E Syndrome

Incidence	More than 200 cases reviewed in the literature
Inheritance	Autosomal dominant (AD) with variable expressivity, sporadic forms, autosomal recessive (AR; rare)
Molecular defect	Dominant-negative mutations in STAT3 (AD and sporadic cases); Dock8, Tyk2 kinase (AR)
Clinical manifestations	"Cold" cutaneous skin abscesses and furuncles Chronic eczematoid dermatitis Mucocutaneous candidiasis Staphylococcal pneumonia, pneumatoceles Chronic cutaneous viral infections (AR) Fungal superinfection of lung cysts Coarse facies (AD) Delayed shedding of primary teeth (AD) Scoliosis (AD) Recurrent fractures (AD) Hyperextensible joints (AD) Craniosynostosis (AD) Vascular disease (AD) Severe allergies (AR)
Laboratory evaluation	Serum immunoglobulin (IgE) >2500 IU/mL Peripheral blood eosinophilia
Differential diagnosis	Atopic dermatitis Wiskott-Aldrich syndrome, DiGeorge syndrome Hypergammaglobulinemia Chronic granulomatous disease
Therapy	Prophylactic antibiotics for *S. aureus* Aggressive treatment of acute infections with parenteral antibiotics Surgical drainage of deep infections and resection of lung cysts Monitoring for scoliosis, fractures, vascular disease, malignancy
Prognosis	Generally good if managed aggressively

(often greater than 2000 IU/mL), serious recurrent staphylococcal infections of the skin and lower respiratory tract, pneumatoceles, chronic pruritic dermatitis, and skeletal and dental abnormalities.[102,980-986] The key features of HIES are summarized in Box 22-12. Neutrophils from patients with this syndrome exhibit a variable, but at times severe, chemotactic defect.[910,981,987,988] This syndrome was originally known as Job syndrome when it was first reported in 1966 in two red-haired, fair-skinned females who had hyperextensible joints and "cold" abscesses that lacked the usual characteristics of inflammation.[980] It is now appreciated that only a small fraction of patients with HIES have red hair or hyperextensible joints, and it may be that Job syndrome is a variant subset of HIES. AD and sporadic cases account for the majority of cases, and HIES is now known to result from dominant negative mutations in STAT-3.[989,990] The more rare AR forms of HIES result from mutations in genes encoding DOCK8, a guanine nucleotide exchange factor, or less commonly TYK2, a JAK family member, and are associated with more profound impairments in lymphocyte function.[983,984,991-994]

The clinical manifestations of HIES are often severe and usually become apparent during infancy. Staphylococcal furuncles of the head and neck as well as chronic dermatitis are seen most often in younger patients. The skin abscesses in HIES typically lack erythema (cold abscesses). Chronic candidiasis of the mucosa and nail beds is also common and can occur in children. Recurrent staphylococcal pneumonia is a common problem as patients grow older and can be complicated by the formation of persistent pneumatoceles that can become superinfected with *Haemophilus influenzae*, gram-negative bacteria, or *Aspergillus*. Chronic infections of the ears, sinuses, and eyes (keratoconjunctivitis) are seen, and septic arthritis and osteomyelitis have been observed. Nonimmunologic manifestations of HIES include dental and bone abnormalities. Delayed shedding of or failure to shed primary teeth occur in the majority of patients. Hyperextensible joints and scoliosis are common. Osteopenia of unknown etiology is observed many patients, and there is also an increased risk of fractures of the long bones and the vertebral bodies, even in the absence of osteopenia.[983] Vascular abnormalities, including aneurysms, tortuosity of middle-sized arteries, and hypertension are also common. Coarse facial features characterized by a broad nasal bridge and a prominent nose are evident in the majority of patients by the time they reach the teenaged years. Craniosynostosis can also occur.

Patients with AR HIES additionally have recurrent or chronic cutaneous viral infections that include Molluscum contagiosum, human papilloma virus, herpes simplex, and varicella, and increased susceptibility to atypical mycobacterial infection.[986,991,992] Significant neurologic sequelae are reported, ranging from partial facial paralysis to hemiplegia.[991] In contrast to AD HIES, pneumatoceles are not seen, nor are skeletal abnormalities, dental problems, or the characteristic facies. However, unlike in AD HIES, patients who are *DOCK8*-deficient can develop asthma and severe allergies, including to foods.

HIES is associated with increased risk of malignancies, particularly *DOCK8* deficiency including non-Hodgkin lymphoma and cancers of the vulva, liver, and lung.[985,986]

The identification of gene defects affecting cytokine signaling in HIES have helped explain its pathogenesis and multisystem manifestations, particularly in the AD form. The associated dominant-negative mutations in STAT3 are located primarily in regions that interact with other proteins or with DNA.[989,990] This interferes with the activity of wild-type STAT3 and results in a complex pattern of altered cytokine signaling and impaired T-helper type 17 (TH17) cell differentiation.[103,985] Both proinflammatory (IL-6) and antiinflammatory cytokines are regulated by STAT3 and thus explain how both too little (e.g., cold abscesses) as well as excessive responses (e.g., enhanced IgE production) might occur. Defective STAT3 signaling impairs differentiation of TH17 cells, which are important for control of mucocutaneous candidiasis. Keratinocytes and bronchial epithelial cells are particularly dependent on TH17 cytokines to secrete defensins and chemokines, which may explain the frequent skin and lung infections. Skeletal defects that are hallmarks of HIES may reflect defective STAT3 signaling in osteoblasts and osteoclasts. Inactivation of IL-11 signaling may explain the dental abnormalities and craniosynostosis.[985] The etiology of impaired neutrophil chemotaxis often seen in these patients, however, remains uncertain.[910,981,987,988]

Patients with AR HIES who have mutations in Tyk2 exhibit additional defects in IL-12 and IFN-α signaling.[992] AR HIES mutations affecting *DOCK8,* which regulates cytoskeletal rearrangements involved in migration, adhesion and growth, lead to defective CD4+ T-cell priming because of impaired dendritic cell migration, and also impair STAT3 activation in B cells. These differences help explain the broader spectrum of infections and other symptoms seen in AR HIES.[994]

The diagnosis of HIES should be considered in any child with the aforementioned clinical history. Almost all patients have peripheral eosinophilia. A markedly elevated polyclonal serum IgE, or at least 2500 IU/mL, is a constant laboratory finding, although IgE levels can fluctuate over time and occasionally decrease to the normal range.[983] Despite the impressive elevations in serum IgE (up to 150,000 IU/mL), this laboratory finding alone is not diagnostic, because comparably high serum levels of IgE can be seen in patients with atopic dermatitis. Because many patients with atopic dermatitis suffer from superficial skin infections and eczema, this disorder must be considered in the differential diagnosis of HIES. The two can be distinguished from each other because of the severe and recurrent nature of the staphylococcal furuncles and the pneumonias seen in HIES. A HIES scoring system developed by the National Institutes of Health can be helpful.[983] DNA testing should be used to make a definitive diagnosis.

Treatment of HIES is largely supportive.[984,985,994] One of the mainstays of therapy for HIES is the use of prophylactic antibiotics such as dicloxacillin or trimethoprim/sulfamethoxazole. These drugs can help prevent staphylococcal infections and should be prescribed at the time of diagnosis. Bleach baths or chlorhexidine washes can diminish colonization by *S. aureus* and reduce abscess formation. Pneumonias and other deep-seated infections should be treated aggressively with parenteral antibiotics. Patients with HIES are unusually predisposed to developing pneumatoceles as a result of staphylococcal lung infections. If these lesions persist, antifungal prophylaxis should be considered. Intravenous IgG infusions have shown some success in management of HIES.[984,994] Delayed shedding of primary teeth may necessitate extraction. Patients should be carefully monitored for scoliosis, and skeletal fractures can occur even after minor trauma. Patients should also be assessed for hypertension and other vascular disease. If infections and their complications are managed aggressively, the prognosis for patients with AD HIES syndrome is good. HSCT may be a consideration in AR HIES because of its higher morbidity and mortality, and has been used successfully in *DOCK8* deficiency.[994] Several patients with AD HIES also received transplants for treatment of lymphoma, with resolution of both immunologic and nonimmunologic features of HIES reported.[985]

Neutrophil Actin Dysfunction

Primary defects in neutrophil actin polymerization are exceedingly rare. The first such case, described by Boxer and colleagues in 1974, was a male infant who suffered from recurrent skin infections caused by *S. aureus* and a cutaneous-cecal fistula complicated by *Streptococcus faecalis* sepsis.[995] Despite a marked neutrophilia, sites of infections were devoid of neutrophils and healed slowly. The patient's neutrophils showed markedly diminished chemotaxis and a decreased capacity to ingest serum-opsonized particles. He underwent a bone marrow transplantation with transient engraftment of normally functioning neutrophils but succumbed to infectious complications. The underlying defect in this patient appeared to involve neutrophil actin or an ABP. Neutrophils from his parents and a sibling had decreased actin polymerization in vitro. Neutrophils from family members also had intermediate levels of and decreased expression of the Mac1 integrin (CD11b/CD18),[996,997] raising the question of whether the neutrophil actin dysfunction in the proband was a variant of LAD I. However, actin filament assembly is normal in patients with LAD I.[997] Alternatively, a primary actin-associated defect might alter cell surface expression of the integrins.

Coates and coworkers have reported a male infant of Tongan descent who was afflicted with severe skin and mucosal infections.[998] At the age of 2 months, he was found to have hepatosplenomegaly, moderate thrombocytopenia, recurrent pulmonary infiltrates, and a lingual ulcer that grew *Candida tropicalis*. Neutrophils had normal cell surface expression of CD11b but exhibited abnormalities in a wide range of motile behaviors, including chemotaxis, phagocytosis, and spreading on glass. Morphologically, the neutrophils displayed thin, filamentous projections of membrane with an underlying abnormal cytoskeletal structure. Biochemical studies revealed markedly defective actin polymerization, and a severe deficiency of an 89-kD protein along with a markedly elevated level of a 47-kD protein. Hence, this disorder has been referred to as neutrophil actin dysfunction with 47- and 89-kD protein abnormalities (NAD 47/89). The 47-kD protein was identified as lymphocyte-specific protein (LSP) 1,[999] an actin-binding protein present in normal neutrophils. Neutrophils from the patient's parents showed a partial defect in actin polymerization and intermediate abnormalities in the levels of LSP1 and the 89-kD protein. These observations, along with a history of previously affected siblings, suggest that NAD 47/89 is an AR disorder. The patient received an allogeneic bone marrow transplant at the age of 7 months with resolution of thrombocytopenia and neutrophil dysfunction.

Markedly impaired neutrophil chemotaxis associated with a heterozygous point mutation in β actin was reported by Nunoi and colleagues in a female patient with recurrent infections, stomatitis, photosensitivity, and mental retardation.[1000] The defect lies within a domain that binds to profilin and other actin-regulatory molecules, and the mutant β actin may interfere with normal actin function in a dominant-negative manner. Interestingly, formyl peptide-induced superoxide production was also decreased in patient neutrophils, suggesting that actin function is important for normal NADPH oxidase assembly.

Localized Aggressive Periodontitis

Localized aggressive periodontitis (LAP), previously known as localized juvenile periodontitis, is a distinct clinical entity characterized by severe alveolar bone loss localized to the first molars and incisors, with an onset around the time of puberty.[1001-1003] LAP appears to be an acquired disorder in some patients and an inherited disorder in others, clustering in families. Defective neutrophil chemotaxis has been identified in vitro in approximately 70% of patients with LAP.[1001,1004-1007] Neutrophil chemotactic activity is not restored in vitro or after the patient is treated for periodontal infection, suggesting a genetic disorder affecting chemotactic receptors. An approximate twofold decrease in the total number of receptors for formyl peptides and C5a is reported for some patients who have LAP.[1005,1008] Other studies indicate that factors elaborated by periodontopathic bacteria may secondarily alter leukocyte function and depress chemotaxis (e.g., *Actinobacillus actinomycetemcomitans, Capnocytophaga* species, and *Bacteroides* species); susceptibility to these factors may also have a genetic component. Recent studies suggest that inflammatory signaling in LAP neutrophils is dysregulated and can lead to hyperinflammatory responses that may contribute to increased periodontal breakdown.[1003,1009,1010]

The diagnosis of LAP should be suspected in any adolescent in whom there is unusually severe and destructive alveolar bone loss involving the first molars and incisors. From a diagnostic point of view, it is important to bear in mind that many qualitative and quantitative neutrophil disorders are associated with periodontal disease that at times may be severe. The differential diagnosis should include LAD, CGD, CHS, leukemia, chronic neutropenia, and CyN.

Neonatal Neutrophils

Although most infants are able to defend themselves successfully against microbial challenges, they are nonetheless at increased risk for development of severe bacterial infections, particularly sepsis, pneumonia, and meningitis caused by group B streptococci.[1011] The risk of infection and the rate of mortality from pyogenic infections are even greater in premature infants. Thus the development of innate immunity in neonates has been the subject of intense investigation for many years.[1011-1014] There is general agreement that various aspects of the neonatal immune response are impaired, including cellular cytotoxic mechanisms and cytokine generation. Defects in neutrophil adherence, chemotaxis, phagocytosis, and bacterial killing all have been reported.[1012-1014] Formation of NETs is also impaired.[376] Compounding these functional defects in neonates is a deficiency of antibodies directed against organisms that typically infect infants. Furthermore, neonates can easily exhaust bone marrow reserves of granulocytes and develop neutropenia in the midst of severe pyogenic infections, as discussed in the previous section.

The most important of the functional defects, at least from a clinical point of view, appears to be the depressed chemotactic ability of neonatal neutrophils and their adhesion. Compared to adult cells, the directed migration of neonatal neutrophils toward a variety of chemotactic agents (C5a, formyl peptides, and bacterial extracts) is reduced by approximately 50% for the first several weeks of life.[1012,1015-1017] The biochemical basis for the diminished chemotaxis does not appear to be related to abnormalities in the number or affinity of either the C5a or formyl peptide receptor.[1012,1017] Although cell surface expression of the β_2 integrin Mac-1 was found to be normal in neonatal neutrophils, total cellular Mac-1 is decreased in neonatal neutrophils.[1018] Because internal membrane stores serve as an intracellular pool for Mac-1 (see Table 22-3), the overall reduction in cellular Mac-1 could explain its diminished upregulation after exposure to chemotactic concentrations of C5a and formyl peptides.[1019,1020] Preterm infants also have decreased levels of neutrophil PSGL-1, and their endothelial cells exhibit diminished upregulation of ICAM-1, E-selectin, and reduced neutrophil binding.[1021] Additional biochemical defects in neonatal neutrophils that may contribute to impaired chemotaxis and adhesion is diminished polymerization of F-actin after stimulation[1022] and decreased amounts of the Rac2 GTPase.[1023] Finally, defects in chemoattractant-induced NF-κB and calcium responses by neonatal neutrophils are reported.[1012,1024]

Other Disorders of Neutrophil Chemotaxis

A syndrome of severe neutrophil dysfunction can result from dominant-negative mutations in the small GTPase Rac2. This was first characterized in a male infant who was born to unrelated parents and experienced recurrent rapidly progressive soft-tissue infections, including a perirectal abscesses and a necrotic periumbilical infection associated with poor formation of pus and neutrophilia.[97-99] Although suggestive of LAD I, expression of $ß_2$ integrins and fucosylated cell surface proteins were normal. Chemoattractant-induced neutrophil functions, including F-actin formation, chemotaxis, degranulation, and the respiratory burst were markedly defective, along with defects in phagocytosis and L-selectin–mediated adhesion.[97,99] Responses to other agonists were normal. This constellation of functional abnormalities resembled those described for gene-targeted mice lacking the hematopoietic-specific GTPase, Rac2.[321,1025] This patient was heterozygous for a point mutation in the Rac2 gene that affects the guanine nucleotide-binding pocket, which apparently exerts a dominant-negative effect on wild type Rac2 to interfere with normal signal transduction.[97,99] Neither parent had the mutant Rac2 allele. The patient was successfully treated by an HLA-matched marrow transplant from a sibling. The clinical history, neutrophilia, and functional neutrophil defects in this patient are very similar to those seen in a female infant described in an earlier report.[1026] This patient was the first child of nonconsanguineous healthy parents, both originating from India, and suffered from chronic omphalitis and otitis media secondary to *S. aureus*, buccal candidiasis, and an internal cecal fistulation that ultimately lead to death from gram-negative sepsis at 8 months of age. Newborn screening for T-cell lymphopenia using the T-cell receptor excision circle assay recently identified another infant with a dominant-negative mutation in Rac2 who underwent successful cord blood transplantation.[938]

A study of 240 patients with a significant history of recurrent infection generally requiring at least one hospitalization identified 10 patients, all children, with a consistent marked reduction chemotactic activity in vitro that was not associated with any other neutrophil abnormalities.[1027] In 6 of these patients, a partial reduction in chemotactic activity was also seen in either the mother or a sibling. Similar findings were reported in a more recent study.[910] However, other than for the disorders previously discussed, well-defined clinical entities in which defective neutrophil chemotaxis plays a predominant role in impaired host resistance to bacteria and fungi have not been established. In part, this is related to the difficulties in performing and interpreting in vitro assays of adhesion and chemotaxis except in specialized research settings. Biochemical approaches to delineating a specific abnormality are also difficult because of the complex nature of the chemotactic response.

Disorders of Opsonization And Ingestion

Clinical disorders of recognition fall into two major categories: humoral and cellular. In the former, plasma-derived opsonins are deficient or absent and result in incomplete opsonization. In contrast, the cellular disorders are characterized by defective receptors for opsonins or by abnormalities in the actin cytoskeletal system responsible for microbial ingestion.

Humoral Disorders of Opsonization

Primary B-cell deficiencies result in the decreased or absent production of immunoglobulins, most commonly IgG. Patients afflicted with these antibody-deficiency syndromes suffer from recurrent infections with pyogenic bacteria such as *S. aureus*, pneumococci, and *H. influenzae*. One of the major functional abnormalities in these disorders is the defective opsonization of pathogenic microorganisms. As a result, these microbes are not efficiently cleared by the host phagocytic system. A variety of clinical disorders may lead to an antibody deficiency, including deficiencies in specific IgG subclasses; these are discussed in Chapter 24.

Complement deficiencies also can result in recurrent infections, particularly when they involve those factors shared by both the classic and the alternative pathways. Therefore patients with deficiencies of C1, C2, or C4 have relatively minor problems with infections, because the alternative pathway remains intact. In the case of C3, on the other hand, recurrent infections are much more common, since this is the protein that is the direct precursor of two major complement opsonins: C3b and C3bi. Two forms of C3 deficiency have been described, and both are quite rare. In one, there is a congenital deficiency of C3 inherited in an AR manner that has been described in approximately 20 patients.[1028-1032] Heterozygotes contain half the normal levels of C3 but do not suffer from infections. The molecular genetic basis of the C3 deficiency has been identified in several families, and the mutations are heterogeneous.[1031,1032] A second type of C3 deficiency is caused by unchecked catabolism of C3 resulting from the absence of a C3 protease inhibitor.[1033] In both types of C3 deficiencies, the majority of patients suffer from recurrent pyogenic infections caused by encapsulated bacteria such as pneumococci. Patients with deficiencies of the terminal complement components (C5, C6, C7, C8, or C9) are particularly susceptible to infections with meningococci or gonococci. Infections in individuals who are complement deficient should be treated with the aggressive use of antibiotics, and immunization against *H. influenza*, *S. pneumoniae*, and *Neisseria meningitidis* may be helpful.

Approximately 5% of the population have low serum levels of MBL, also known as mannose binding protein. MBL is a serum lectin secreted by the liver and functions as a soluble PRR, binding to mannose sugars present on the surface of bacteria, fungi, and some viruses.[329,331,332] Bound MBL activates the complement cascade to mediate opsonization of a broad range of microbes with C3 cleavage products. The incidence of MBL deficiency is higher in infants with frequent unexplained infections, chronic diarrhea, and otitis media. It has been proposed that MBL serves as a primitive antibody of broad specificity to provide an important defense mechanism during the time period when maternal antibody levels have waned yet the antibody repertoire of the infant is still immature.[329,331,332] MBL deficiency is associated with AD inheritance of point mutations in a collagen-like domain of the MBL polypeptide.[1034-1036] These mutations decrease MBL levels by interfering with the normal polymerization of MBL subunits to form the oligomeric structure required for complement activation. A polymorphism in the promoter of the MBL gene has also been described that can influence MBL levels.[329] Clinical illness associated with MBL deficiency may not be limited to infants. In a recent report, MBL deficiency was the only identifiable immune defect in four adults with recurrent infections as well as in one patient who also had IgA deficiency.[1037] The spectrum of illness included recurrent skin abscesses, chronic cryptosporidial diarrhea, meningococcal meningitis with recurrent herpes simplex, and fatal *Klebsiella* pneumonia. Three of the five adults were homozygotes for mutant MBL alleles. Decreased MBL levels are seen in some populations, for example in sub-Saharan Africa, suggesting that low levels of this protein may be beneficial in certain settings. For example, low levels of MBL may partially protect against mycobacterial infections.[329]

Cellular Disorders of Ingestion

Patients with LAD I show a marked abnormality in phagocytosis of C3bi-opsonized particles, since the Mac-1 β_2 integrin (CD11b/CD18) that is deficient in LAD I functions as the C3bi receptor (see Tables 22-2 and 22-5). Patients with neutrophil actin dysfunction also show abnormal ingestion, since actin assembly plays a critical role in the formation of phagosomes.

A deficiency of FcγRIa has been described in four members of a Dutch family.[1038] The monocytes from the affected family members did not bind IgG with high affinity. However, these individuals did not show an increased susceptibility to infection despite this receptor deficiency. There is an incidence of 4 in 3377 in the

French population for the complete absence of FcγRIIIb, and neutrophils from affected individuals type as neutrophil-specific antigen (NA)-null.[1039] None of these individuals exhibit any increased incidence of infection, although infants of women with the NA-null phenotype can develop alloimmune neutropenia because of placental transmission of anti-FcγRIIIb antibodies. Similar findings were also reported in a study of 21 individuals from 14 families with FcγRIIIb deficiency in the Netherlands.[325] Complete absence of the FcγRIIIb gene was found in all kindreds studied. Three of the women who had multiple pregnancies lacked antineutrophil antibodies, suggesting that neonatal alloimmune neutropenia does not always develop in this setting. Marked deficiency in neutrophil FcγRIIIb has also been observed in patients with paroxysmal nocturnal hemoglobinuria (PNH),[1040] an acquired stem cell disorder caused by a defect in the biosynthesis of GPI membrane anchors. Since neutrophil FcγRIIIb is linked to the plasma membrane by means of a GPI anchor,[1041] this receptor is unable to insert in the cell membranes in patients with PNH. Decay-accelerating factor and acetylcholinesterase are also deficient in the membranes of patients with PNH, because these two proteins are also anchored by GPI moieties. Neutrophils from patients with PNH undergo a normal oxidative burst in response to IgG-coated latex particles.[1041] Thus there appears to be sufficient redundancy in the function of Fc and complement receptors to permit normal phagocytic function in these cases of FcγRI and FcγRIIIb deficiencies.

Allelic polymorphisms in FcγRIIa (131H vs. 131R) and in FcγRIIIb (NA1 vs. NA2) may each contribute to a subtle defect in the host response to encapsulated microorganisms. The polymorphism in amino acid 131 in FcγRIIa affects binding to IgG$_2$, with *H* referring to *high responder* and the ability to bind to this IgG subclass. The 131H versus 131R polymorphism is seen in approximately equal rates in the Caucasian population, but are distributed in a 3 : 1 ratio in Japanese and Chinese populations.[325] FcγRIIa131H allele is the only FcγR able to mediate efficient phagocytosis of IgG$_2$-opsonized bacteria, and the FcγRIIa 131H/131H genotype in children was associated with a lower incidence of infections with encapsulated bacteria.[325] The NA1 polymorphism in the FcγRIIIb receptor, which affects receptor glycosylation, is associated with more efficient phagocytosis of IgG-opsonized particles compared to the NA2 allele.[325,1042] The allelic frequency of the NA1 allele is approximately 0.33 compared to roughly 0.64 for the NA2 allele in Caucasians, but this ratio is reversed in Japanese and Chinese populations. Patients who are homozygous for both the FcγRIIa131R and the FcγRIIIb NA2 alleles appear to be at higher risk for meningococcal meningitis.[1043]

Disorders of Neutrophil Granules

Phagocytes kill microorganisms using a variety of cytotoxic compounds. These include a host of preformed antimicrobial polypeptides that are stored within intracellular granules and released into the phagocytic vacuole upon phagocytosis. The importance of granule contents in host defense is attested to by two clinical syndromes associated with disorders of neutrophil granules, CHS, and SGD.

Chediak-Higashi Syndrome

CHS is a rare, AR multiorgan disease resulting from defects in granule morphogenesis and is characterized by partial oculocutaneous albinism, frequent bacterial infections, giant lysosomes in granulocytes, and (in some patients) a mild bleeding diathesis as well as peripheral and cranial neuropathies associated with decussation defects at the optic chiasm (Box 22-13).[634,1044-1049] Ten types of oculocutaneous albinism have been described in humans, and CHS is one of the tyrosinase-positive forms that has been designated as type VIB. Because granule defects also affect cytotoxic T-cell and NK-cell function,

Box 22-13 Summary of Chédiak-Higashi Syndrome

Incidence	More than 200 cases described
Inheritance	Autosomal recessive
Molecular defect	Defect in granule morphogenesis in multiple tissues as a result of mutations in the *CHS1* gene, which encodes a lysosomal trafficking protein
Pathogenesis	Giant coalesced azurophilic/specific granules in neutrophils resulting in ineffective granulopoiesis and neutropenia, delayed and incomplete degranulation, and defective chemotaxis
Clinical manifestations	Partial oculocutaneous albinism Recurrent severe bacterial infections (usually *S. aureus*) Gingivitis and periodontitis Cranial and peripheral neuropathies (muscle weakness, ataxia, sensory loss, nystagmus) Hemophagocytic lymphohistiocytosis (HLH; accelerated phase)
Laboratory evaluation	Giant granules in peripheral blood granulocytes and in bone marrow myeloid progenitor cells Widespread lymphohistiocytic infiltrates in accelerated phase
Prenatal diagnosis	Demonstration of giant granules in fetal blood neutrophils or cultured amniotic cells
Differential diagnosis	Other genetic forms of oculocutaneous albinism Giant granules can be seen in acute and chronic myelogenous leukemia
Therapy	Prophylactic trimethoprim/sulfamethoxazole Parenteral antibiotics for acute infections Ascorbic acid (200 mg/day for infants; 6 g/day for adults) Steroids, cyclosporine, etoposide for HLH Bone marrow transplantation before or at beginning of HLH
Prognosis	Most patients die of infection or complications of HLH in the accelerated phase during the first or second decade of life unless transplantation performed

CHS is associated with HLH in the "accelerated" phase of the disease that often develops after the first or second decade of life.[634,1048-1050]

CHS is caused by a fundamental defect in granule morphogenesis that results in abnormally large granules in multiple tissues. The most extensively studied of the affected cells are the neutrophils. In the early stages of myelopoiesis, some of the normally sized azurophil granules coalesce to form giant granules[63] that later fuse with some of the specific granules to form huge secondary lysosomes that contain constituents of both granule types.[1051-1053] In addition to this uncontrolled fusion of granules, CHS neutrophils are markedly deficient in neutral proteases,[1054] including two azurophil granule enzymes, cathepsin G and elastase.[1055] In melanocytes, there are giant melanosomes that prevent the even distribution of melanin and result in hypopigmentation of the hair, skin, iris, and ocular fundus. Giant granules are also seen in other leukocytes, Schwann cells, and certain cells in the liver, spleen, pancreas, gastric mucosa, kidney, adrenal gland, and pituitary gland.[634,1047,1049] Disorders similar to human CHS have also been described in many mammalian species, including Aleutian mink, *beige* mice, blue foxes, cats, killer whales, and Hereford cattle.[1046,1047,1056]

Mutations in the *CHS1* gene, believed to normally regulate lysosome biogenesis, accounts for the most cases of CHS.[1057-1059] *CHS1* is on the long arm of chromosome 1 and is homologous to the *bg* locus responsible for the granule defect in *beige* mice.[1060] The *beige* gene was positionally cloned, and termed *LYST* for its presumed function as a lysosomal trafficking regulatory protein.[1057,1059] The encoded CHS/LYST protein is very large (3801 amino acids) polypeptide, and at least one of its functions may be to inhibit lysosome fusion with other intracellular membrane vesicles.[1061] Frameshift and nonsense mutations have been identified in the *CHS1* gene in patients with CHS, with the result of truncated forms of the protein.[1057-1059,1062,1063] Patients with clinically typical CHS that lack identifiable mutations in *CHS1* have been reported, suggesting that additional genetic loci may be affected in some cases.[1064]

Some of the most dramatic examples of the granule defect in CHS are manifested in the various blood cells and are summarized in Box 22-14. A few to a large majority of circulating neutrophils contain giant coalesced azurophil and/or specific granules. These giant granules are often more prominent in the bone marrow than in the peripheral blood, because many of the abnormal myeloid precursors are destroyed before they ever leave the marrow.[1065] Extensive myeloid cell vacuolization, enhanced marrow cellularity, and elevated levels of serum lysozyme all reflect this process of intramedullary granulocyte destruction. As a result, most patients with CHS have a moderate neutropenia with absolute neutrophil counts ranging between 500 and 2000 cells/mm^3.[1044,1045] Monocytes are also affected in CHS and have similar but not identical cytoplasmic inclusions that appear to be ring-shaped lysosomes.[1066] Lymphocytes can also contain giant cytoplasmic granules that contribute to abnormal cytotoxic T-cell and NK-cell function. Finally, CHS platelets have a decreased number of dense granules and a storage pool deficiency of ADP and serotonin.[1067-1070] This abnormality leads to a defect in platelet aggregation and an increased bleeding time manifested clinically as easy bruising, intestinal bleeding, and epistaxis. Most patients with CHS do not have thrombocytopenia until they enter the accelerated phase of the disease (described later in this section).

Box 22-14 Hematologic Manifestations of Chédiak-Higashi Syndrome

STABLE PHASE

NEUTROPHILS

- Giant, coalesced azurophilic specific granules
- Vacuolization of marrow neutrophils (ineffective myelopoiesis)
- Neutropenia (intramedullary destruction)
- Decreased bactericidal activity
  - Decreased chemotaxis in vivo and in vitro
  - Delayed and incomplete degranulation

MONOCYTES/MACROPHAGES

- Ring-shaped lysosomes
- Decreased chemotaxis

LYMPHOCYTES/NATURAL KILLER CELLS

- Giant cytoplasmic granules
- Diminished natural killer function
- Diminished antibody-dependent cell-mediated cytolysis

PLATELETS

- Giant cytoplasmic granules may be seen
- Normal platelet count
- Increased bleeding time because of abnormal aggregation caused by storage pool deficiency of adenosine diphosphate and serotonin

ACCELERATED PHASE (HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS)

- Hepatosplenomegaly
- Bone marrow infiltration
- Hemophagocytosis by histiocytes
- Worsening neutropenia, thrombocytopenia, and anemia as a result of the first three manifestations

The infections usually encountered with CHS involve the skin, respiratory tract, and mucous membranes and are caused by both gram-positive and gram-negative bacteria as well as by fungi. The most common organism is *S. aureus*. These infections are often recurrent and can be fatal. Gingivitis and periodontitis are common. The skin is also susceptible to severe sunburns, and photosensitivity in bright light is common.

The neutrophil defects are primarily responsible for the propensity to bacterial infection. In addition to the moderate neutropenia, several defects in neutrophil function lead to impaired bactericidal activity. First, chemotaxis is markedly depressed, whether measured in vivo by the Rebuck skin window or using in vitro chemotaxis assays.[1045,1071] The large granules appear to interfere with the ability of neutrophils to travel through narrow passages such as those between endothelial cells. Second, degranulation is delayed and incomplete in CHS neutrophils.[1072,1073] Third, the marked deficiency of antimicrobial proteins such as cathepsin G probably contributes to the diminished bactericidal potency of CHS neutrophils.[1073] Finally, decreased expression of

Mac-1 (CD11b/CD18) in CHS neutrophils may also play a role.[1074]

Contributing to the enhanced susceptibility to infection are abnormalities in monocytes, lymphocytes, and NK cells. Monocytes, like neutrophils, exhibit decreased chemotaxis.[1075] Peripheral blood CHS lymphocytes demonstrate diminished ADCC of tumor cells.[1076] Perhaps most important, cytotoxic T-cell and NK-cell cytolytic function is profoundly abnormal in CHS.[1048,1050,1076-1078] This defect not only contributes to the recurrent bacterial infections, but also leads to the development of HLH in the accelerated phase of CHS, which is sometimes precipitated by a herpes-type virus such as Epstein-Barr virus or varicella.[1048,1050,1079]

Those patients who survive the infectious and neurologic problems of the stable phase of CHS have a high risk of progressing to the accelerated phase of the disease, now recognized to be a genetic form of HLH.[1044,1048,1050] HLH results from uncontrolled hyperinflammation and multiorgan dysfunction that can be triggered by viral infections or other stimuli, and typically develops during the first or second decade of life in CHS.[1044,1048,1050] The accelerated phase is characterized pathologically by a diffuse lymphohistiocytic infiltration of the liver, spleen, lymph nodes, and bone marrow, and the outcome for the patient is uniformly fatal if not treated.[1048,1050] The accelerated phase is heralded by hepatosplenomegaly, bone marrow infiltration, and hemophagocytosis that lead to a worsening of the neutropenia and an ever-increasing risk of infection. Thrombocytopenia likewise develops and intensifies the bleeding disorder already present in the platelets.

The diagnosis of CHS should be suspected in any child who shows one or more of the following findings: (1) recurrent bacterial infections of unknown etiology; (2) hypopigmentation of the hair, skin, and eyes; a white forelock can be present; (3) the presence of giant peroxidase-positive lysosomal granules in granulocytes from peripheral blood or bone marrow; (4) mild to moderate neutropenia; (5) easy bruising or nose bleeds despite a normal platelet count; and (6) unexplained hepatosplenomegaly (associated with the accelerated phase of the disease). CHS is usually manifested in infancy or early childhood but may present later when the child is in the accelerated phase. In some patients, the disease may be suspected on the basis of neurologic abnormalities that include ataxia, muscle weakness, decreased deep tendon reflexes, sensory loss, a diffusely abnormal electroencephalogram, and abnormal visual and auditory evoked potentials.[1080,1081] The physician should not be dissuaded from considering the diagnosis of CHS if the patient does not show clear-cut oculocutaneous albinism. Depending on the skin coloration in the family, the only manifestations of the albinism may be a metallic sheen in the hair (which can vary from blond to dark brown) and a lighter skin color than that seen in siblings. In younger patients, there is likely to be a cartwheel distribution of pigment in the iris and an abnormal red reflex.

The diagnosis of CHS is made on the basis of giant peroxidase-positive lysosomal granules found in blood or bone marrow myeloid cells. In some cases, relatively few abnormal granulocytes are seen in the peripheral blood, presumably because of extensive intramedullary destruction of myeloid precursors, and a bone marrow aspirate may be necessary to identify the large lysosomes. Microscopic examination of the hair reveals giant melanin granules. In the accelerated phase, biopsies of the liver, spleen, and lymph nodes reveal diffuse infiltrates of lymphohistiocytic cells. For prenatal diagnosis, the observation of large abnormal granules in neutrophils and larger than normal acid-phosphatase lysosomes in cultured amniotic and chorionic villus cells has been used.[1082] Microscopic examination of fetal hair shafts is also reported.[1083]

The differential diagnosis for CHS includes other genetic forms of partial albinism.[645] These include Griscelli syndrome,[640] which is distinguished from CHS by the lack of giant cytoplasmic granules in neutrophils and the finding of large pigment clumps in hair shafts and accumulation of mature melanosomes in melanocytes. Patients with Griscelli syndrome also typically develop HLH, again because of defective cytolytic T- and NK-cell function.[1048,1050,1084] Hermansky-Pudlak syndrome is another disorder of partial albinism but is characterized by platelet function defects and an associated bleeding diathesis. Giant granules resembling those seen in CHS can be seen in both acute and chronic myelogenous leukemias[1085-1087] and should not be confused with those seen in CHS.

The management of the stable phase of CHS primarily involves treatment of infectious complications. Prophylactic trimethoprim/sulfamethoxazole may be beneficial. Infections should be treated vigorously with appropriate intravenous antibiotics. Treatment with high doses of ascorbic acid (20 mg/kg/day) has been reported to cause clinical improvement as well as improved function of neutrophils in vitro (neutrophil chemotaxis and/or bactericidal function).[1088,1089] Although there is some disagreement in the literature regarding the efficacy of ascorbic acid,[1090] it seems reasonable to try this medication given its safety in moderate doses. NK-cell function appears to remain abnormal even after ascorbate therapy.

The treatment of HLH (accelerated phase) has improved in recent years using combinations of drugs that suppress the function of activated macrophages and T cells, followed by allogeneic HSCT. Regimens for HLH include corticosteroids, cyclosporine A, and etoposide and are recommended for the accelerated phase of CHS.[1048,1050] Active therapy should be maintained until bone marrow transplantation can be performed. The only curative therapy is bone marrow transplantation with matched related or unrelated donor grafts.[1048,1050] This procedure is ideally performed before the onset of the accelerated phase. Transplantation does not prevent the progressive neuropathy associated with CHS.[1091]

Specific Granule Deficiency

SGD is an extremely rare congenital disorder of neutrophil function characterized by recurrent bacterial infections and multiple abnormalities in neutrophil structure and composition, including absent specific granules and bilobed nuclei.[1092,1093] Despite its rarity, SGD is an important part of the differential diagnosis in patients with suspected phagocyte immunodeficiencies and provides unique insights into the transcriptional regulation of granule biogenesis and the functional roles of lactoferrin, vitamin B_{12}-binding protein, and other specific granule constituents in host defense. Six patients have been reported with SGD.[56,1055,1094-1108] The inheritance appears to be AR,[1103,1104,1109] or in one case, AD.[1108]

The key features of SGD are summarized in Box 22-15. Clinically, patients with this disorder suffer from indolent, smoldering cutaneous infections punctuated by episodes (sometimes prolonged) of severe infections involving the lungs, ears, lymph nodes, and the deeper structures of the skin. Lung abscesses and mastoiditis have been reported as complications of these infections. *S. aureus*, *P. aeruginosa*, *Proteus* species, other enteric gram-negative bacteria, and *C. albicans* appear to be the major pathogens. Further complicating the clinical course in some of the patients is the presence of neutropenia that is either intermittent and mild[1094,1096] or prolonged and severe.[1106]

Box 22-15 Summary of Neutrophil Specific Granule Deficiency

Incidence	Six cases reported
Inheritance	Autosomal recessive
Molecular defect	Protein deficiencies in azurophilic granules (defensins), specific granules (lactoferrin, vitamin B_{12}-binding protein, gelatinase), and secretory vesicles (alkaline phosphatase) suggest a common defect in regulation of the production of these proteins in myeloid cells. Eosinophil specific granules also deficient in protein contents. Mutations in the myeloid transcription factor CCAAT/enhancer-binding protein (C/EPB) ε identified in several patients.
Pathogenesis	Recurrent infections result from the combined effect of deficiencies in microbicidal granule protein (e.g., defensins and lactoferrin) and abnormal chemotaxis, perhaps as a result of failure to upregulate surface β_2 integrins and chemotactic peptide receptors from granule stores
Clinical manifestations	Recurrent (sometimes indolent) pyogenic infections of the skin, ears, lungs, and lymph nodes that may have diminished neutrophil infiltration; onset usually during infancy
Laboratory evaluation	Absent or empty specific granule vesicles in neutrophils by electron microscopy (by light microscopy, granules appear absent) Bilobed nuclei resembling the Pelger-Huët anomaly are often seen in neutrophils Severe deficiency of neutrophil lactoferrin, vitamin B_{12}-binding protein, defensins, and alkaline phosphatase (by histochemical assay)
Differential diagnosis	Acquired specific granule deficiency (e.g., thermal burns or myeloproliferative syndromes)
Therapy	Prophylactic antibiotics Parenteral antibiotics for acute infections Surgical drainage or resection of refractory infections
Prognosis	With appropriate medical management, patients can survive into their adult years

Functional defects identified in patient neutrophils include a marked abnormality in chemotaxis that is observed in vivo by the Rebuck skin window technique.[1094,1096,1097,1104] In vitro measurements of neutrophil killing of *E. coli* and *S. aureus* show a moderate impairment despite the presence of a normal respiratory burst.[1094-1097,1104,1107] Patient neutrophils adhere normally to plastic surfaces[1095,1104] but exhibit slightly diminished sticking to nylon fibers and endothelial cells.[1097] Degranulation of both azurophil and (to the extent that they are present) specific granules also appears to be normal.[1095,1097,1104]

At least three cellular compartments are affected by the underlying molecular defect(s) in SGD: the nucleus, specific granules, and azurophil granules. Approximately half or more of the peripheral blood neutrophils in SGD have nuclei that resemble those seen in the Pelger-Huët anomaly. The nucleus has a kidney-shaped, bilobed configuration that is flawed by a series of microlobulations and clefts apparent by electron microscopy.[1096,1097,1104] On a Wright stain of peripheral blood, neutrophils appear to be devoid of the pink-staining specific granules. By electron microscopic analysis, however, it is apparent that the specific granules are not actually absent but are instead present as empty, elongated vesicles that retain their characteristic trilamellar membrane structure and positive staining for complex carbohydrates.[1096,1098,1099,1103] Biochemical measurements of specific granule contents parallel the morphologic studies. Lactoferrin, vitamin B_{12}-binding protein, and gelatinase[1110] are present at levels that are only 3% to 10% of normal.[1095,1097,1104] Thus there appears to be an abortive and incomplete formation of normal specific granules. Azurophil (primary) granules in this disorder are also strikingly abnormal. Although they contain a normal (if not slightly elevated) amount of MPO and are present in normal numbers, they are severely deficient in defensins.[1055] There is also a severe deficiency of alkaline phosphatase activity, which is normally localized to secretory vesicles, in peripheral blood neutrophils[1094,1096,1099,1104] Finally, granule formation also appears to be abnormal in eosinophils. These cells are deficient in three eosinophil-specific granule proteins (eosinophil cationic protein, MBP, and eosinophil-derived neurotoxin), although the corresponding mRNA transcripts are present.[1111]

In view of the multiple deficits in granule matrix contents produced after the promyelocyte stage, it had long been speculated that SGD is caused by an abnormality in biosynthetic regulation of granule (and probably nongranule) proteins during granulopoiesis. This is also consistent with the observation that the SGD neutrophils are severely deficient in defensins. In contrast to other azurophilic granule proteins, which are synthesized at the promyelocyte stage, defensins are produced during the subsequent myelocyte stage (see Fig. 22-1).

At least some cases of SGD result from AR mutations in a transcription factor that regulates gene expression during granulocyte differentiation. Serendipitously, mice generated with a targeted deletion in the myeloid transcription factor C/EBPε exhibit absence of neutrophil secondary granules and their matrix proteins, bilobed neutrophil nuclei, impaired chemotaxis, and increased susceptibility to bacterial infection.[1112-1114] Mutations in the C/EBPε gene have been identified in two patients with SGD to date. In one case, a five base-pair deletion results in a truncated, nonfunctional protein,[1115] whereas a second, unrelated patient was homozygous for a nucleotide insertion in the coding sequence that also leads to the synthesis of a truncated and nonfunctional form of C/EBPε.[1116] However, DNA sequencing of the C/EBPε gene of several other patients with SGD has not revealed abnormalities, suggesting that SGD is a genetically heterogeneous disorder.[1117]

The cellular defects described can explain, at least in part, the observed clinical problems in SGD. The markedly abnormal specific granules and secretory vesicles, which contain intracellular stores of both β_2 integrins[1118-1120] and a chemotactic peptide receptor,[1121] fail to support normal upregulation of these two types of receptors[1101,1104] and may thereby contribute to the chemotactic defect. Furthermore, the severe deficiency of key bactericidal proteins such as lactoferrin and the defensins render the cell less efficient in killing bacteria and *Candida*. Neutropenia, when it does occur, also impairs host defense and appears to be caused by intramedullary destruction of the abnormal neutrophils, as evidenced by their ingestion by marrow macrophages.[1103]

The diagnosis of SGD can be made by light microscopic examination of Wright-stained peripheral blood neutrophils. Electron microscopic studies can confirm the presence of empty specific granule vesicles. Bilobed nuclei and greatly diminished levels of alkaline phosphatase by histochemical analysis also support the diagnosis. In conjunction with these morphologic studies, biochemical and immunologic measurements of lactoferrin, vitamin B_{12}-binding protein, and defensins can be made. As discussed previously, all three of these granule proteins are severely deficient in this disorder. Acquired SGD is observed in myeloproliferative syndromes and after thermal burns.[1092,1122] In these acquired disorders, however, at least a few intact specific granules are still observed microscopically, and the deficiencies of the various granule enzymes are less profound.

As with other neutrophil disorders, prophylactic antibiotics appear to be beneficial based on anecdotal experience. Parenteral antibiotics should be used aggressively for acute infections. With appropriate medial management, patients can survive into their adult years. Malignant transformation of the dysmorphic myeloid cells in this disorder has not been reported.

Disorders of Oxidative Metabolism

The elimination of many pathogens requires oxygen-derived microbicidal compounds that are generated by the phagocyte respiratory burst pathway in response to inflammatory stimuli (see Fig. 22-8). Five clinically recognized defects have been identified in this series of reactions. These include deficiencies in the NADPH oxidase (see reaction 1 in Fig. 22-8), G6PD (reaction 8), MPO (reaction 4), glutathione reductase (reaction 7), and glutathione synthetase (reaction 9).

Chronic Granulomatous Disease

CGD is an inherited disorder of phagocyte function in which the generation of superoxide by the respiratory burst oxidase (see Fig. 22-9) in neutrophils, monocytes, macrophages, and eosinophils is absent or markedly deficient. The disorder occurs with an estimated minimum incidence of approximately 1 in 200,000 individuals in the United States and Europe, making it the most common clinically significant disorder of phagocyte function that is inherited.[1123] CGD is the result of mutations in any one of five essential subunits of the respiratory burst oxidase (see Fig. 22-9; Tables 22-7 and 22-12).[429,438,1124-1126] Although originally described as an X-linked recessive

TABLE 22-12 Classification of Chronic Granulomatous Disease

Component Affected	Inheritance	Subtype[*]	Flavocytochrome *b* Spectrum	NBT Score (% Positive)	Incidence (% of Cases)
gp91^{phox}	X	X91^0	0	0	60
		X91$^-$	Low	80-100 (weak)	5
		X91$^-$	Low	5-10	<1

*The relative frequencies of different types of infections in chronic granulomatous disease (CGD) are estimated from data pooled from several large series of patients in the United States, Europe, and Japan (see text for references). These series encompass approximately 550 patients with CGD after accounting for overlap between reports. The list of infecting organisms is also arranged according to the data in these reports and is not paired with the entries in the first column.

†Infections most commonly seen at initial evaluation.

‡Incidence is higher in some regions.

disorder affecting boys,[1127-1131] approximately one third of CGD is inherited as an AR trait (see Table 22-12).[1123,1132] In more than 90% of patients, superoxide production by activated phagocytes is below 2% of normal or undetectable. Patients with a respiratory burst of 2% to 10% of normal are sometimes referred to as having "variant" CGD.[1133-1135] Other aspects of phagocyte function are normal in CGD, including adherence, ingestion, and degranulation.[1136-1138]

Clinical Manifestations. CGD is associated with a distinctive clinical syndrome that illustrates the importance of the phagocyte respiratory burst in both innate immunity and the inflammatory response.[1123,1139-1156] Patients suffer from often severe purulent bacterial and fungal infections, in many cases caused by organisms that are not ordinarily considered pathogens. The other and distinctive hallmark of this disorder is the propensity to develop chronic inflammatory granulomas that can be of widespread tissue distribution. The majority of patients with CGD manifest symptoms within the first year of life,[1123,1142] although some may remain relatively symptom-free until later in childhood or even adult life.[1157-1162] As discussed later in this section, current management of CGD patients has markedly reduced the overall incidence of infections and other complications along with disease-associated mortality.

Table 22-13 summarizes the types of infections and infecting organisms encountered in CGD. The major sites of infection are those that come into contact with the external environment—lungs, skin, GI tract, and the lymph nodes that drain these organs. Hematogenous seeding can lead to liver abscesses or osteomyelitis. The most common pathogens include *S. aureus*, *Aspergillus* species (most often *A. fumigatus* but occasionally *A. nidulans* and other species),[1163-1167] *Nocardia*, and a variety of gram-negative bacilli, including *Serratia marcescens* and various *Salmonella* species. Members of the *Burkholderia cepacia* complex are aggressive and potentially lethal pathogen in CGD.[1123,1168-1170] Those causing infection in CGD include *B. cenocepacia*, *B. gladioli*, and *B. mallei*, which causes melioidosis in East Asian countries.[1168,1169] *Burkholderia* and *Nocardia* are less commonly seen in Europe compared to North America.[1146] Tuberculosis is seen in endemic regions,[1171] and vaccination with BCG can result in severe localized, or less commonly, disseminated BCG infection[1146,1153,1172]: infections with other atypical mycobacteria are also reported in

CGD.[1173] *Granulobacter bethesdensis,* a member of the gram-negative *Acetobacteraceae* family and previously not associated with human disease, was first identified in a CGD patient with recurrent fevers and a chronic necrotizing deep lymphatic infection.[1174,1175] In many febrile illnesses, no organism can be identified despite extensive culturing. In these cases, it is important to look carefully for the presence of unusual microbes that can occasionally cause serious infections in CGD (see Table 22-13).[1158,1176-1183]

Pneumonia is most commonly caused by *S. aureus, Aspergillus* species, and enteric bacteria. It is common for an organism not to be identified even in lung biopsy specimens. Complications of pneumonia include empyema or lung abscess. Suppurative lymphadenitis, usually involving the cervical nodes, is especially common in younger patients and is typically caused by *S. aureus* and enteric bacilli such as *Serratia* and *Klebsiella*. Staphylococcal skin infections are also common. Hepatic and perihepatic abscesses, usually caused by *S. aureus*, are surprisingly common and should suggest the diagnosis of CGD if it has not already been made.[1184-1187] Bone infections can be particularly problematic in CGD and arise either from direct spread of infections from contiguous sites or from hematogenous spread from more distant locations.[1123,1188] The former type of osteomyelitis is usually seen in ribs and vertebral bodies as a result of invasion by pulmonary *Aspergillus*.[1188] The latter type is more frequently seen in peripheral long and small bones, and is typically caused by *S. marcescens*, *Nocardia* species, and *S. aureus*.[1189] Perirectal infections are extremely difficult to treat in CGD and can lead to fistula formation.[1189,1190] The rare pathogen *Chromobacterium violaceum* is found in brackish waters and is an uncommon but potentially serious cause of soft-tissue infection, pneumonia, or sepsis in CGD patients from the southern United States.[1178,1179,1191] In northern areas, *Francisella philomiragia* in brackish waters can cause sepsis in CGD.[1180,1192]

It has long been recognized that patients with CGD are particularly susceptible to organisms that contain catalase, which prevents the CGD phagocyte from scavenging microbial-generated H_2O_2 for phagosomal killing.[1193] Thus infections with streptococci or *Haemophilus* species, which are typically catalase-negative, are not problematic in CGD. Another possible link among the organisms with increased virulence in CGD is that they are resistant to nonoxidative killing mechanisms of the phagocyte mediated by antibiotic proteins contained within the various granule compartments.[1194]

TABLE 22-14 Chronic Conditions Associated with Chronic Granulomatous Disease

Condition	% of Cases
Lymphadenopathy	98
Hypergammaglobulinemia	60-90
Hepatomegaly	50-90
Splenomegaly	60-80
Anemia of chronic disease	Common*
Underweight	70
Chronic diarrhea	20-60
Short stature	50
Gingivitis	50
Dermatitis	35
Hydronephrosis	10-25
Ulcerative stomatitis	5-15
Pulmonary fibrosis	<10*
Esophagitis	<10*
Gastric antral narrowing	<10
Granulomatous ileocolitis	<10
Granulomatous cystitis	<10
Chorioretinitis	<10
Glomerulonephritis	<10
Discoid lupus erythematosus	<10

*The relative frequencies of the chronic conditions associated with chronic granulomatous disease were estimated from the series of reports listed in Table 22-13.

Chronic conditions associated with CGD are responsible for many of the major complications seen with this disorder[1156] and are summarized in Table 22-14. These include the granulomas that are a distinctive feature of CGD. These lesions contain a mixture of lymphocytes and inflammatory macrophages, some of which may have a foamy lipoid cytoplasm that has a characteristic yellow-brown color. Although not pathognomonic of CGD, the presence of such macrophages in granulomas or other tissue sites should suggest the diagnosis of CGD.[1128,1129,1131,1195] Granulomatous inflammation in some instances reflects an indolent infection because of inadequate phagocyte killing. However, this manifestation is also believed to in part reflect a dysregulated inflammatory response in the absence of respiratory burst–derived oxidants. This leads to abnormally high level of cytokines and other proinflammatory mediators and delayed neutrophil apoptosis at inflammatory sites.[1156,1196-1198] Inefficient phagocyte degradation of debris is also likely to be a contributing factor to chronic inflammation in CGD.[1198] Granulomatous inflammation can develop in response to fungal cell walls independent of active infection.[1198]

Granuloma formation can lead to obstructive symptoms in the upper GI tract, including gastric outlet obstruction that can be confused clinically with pyloric stenosis.[1184,1189,1190,1199,1200] Inflammation can affect the GI tract from the esophagus to the rectum, is associated with a range of symptoms affecting as many as 30% in a referral center,[1189,1201] and is more common in X-linked CGD. A chronic ileocolitis syndrome resembling Crohn disease is seen in approximately 5% to 10% of patients and can lead to a debilitating syndrome of diarrhea and malabsorption; perirectal abscesses are also problematic.[1184,1189,1202] Chronic inflammatory lesions can develop in the urinary bladder walls and can cause a chronic cystitis that can present as dysuria, penile pain, and decreased urine volume.[1203-1207] In one study of 60 patients with CGD, 11 cases of granulomatous inflammation of the bladder wall lesions, ureters, or urethra were seen and accompanied by stricture formation in the latter two sites.[1208] Hydronephrosis can occur as a complication of obstruction.

Other chronic inflammatory complications of CGD include lymphadenopathy, hepatosplenomegaly, and an eczematoid dermatitis,[1142,1209] along with hypergammaglobulinemia, anemia of chronic disease, and short stature (see Table 22-14). Gingivitis and ulcerative stomatitis can be seen.[1210] Destructive white matter lesions in the brain have been also been described.[1211,1212] In CGD-associated chorioretinitis,[1213,1214] a recent study identified bacterial DNA in the chorioretinal scars, suggesting the possibility of an infectious etiology.[1215] Glomerulonephritis has been reported.[1216,1217] Discoid lupuslike skin lesions develop in up to 20% of patients, and occasionally patients develop systemic lupus erythematosus, juvenile rheumatoid arthritis, sarcoidosis, or other autoimmune disorders.[1218-1223] Subtle defects in CGD memory B cells[1224,1225] may influence the development of autoimmune disease in CGD. Interestingly, gene association studies have identified links between variant alleles encoding cytosolic NADPH subunits and inflammatory bowel disease, rheumatoid arthritis, and systemic lupus erythematosus, consistent with the notion that NADPH oxidase activity normally exerts a suppressive effect on inflammation and autoimmunity.[1156,1226]

The severity and pattern of complications of CGD are heterogeneous. Patients with p47^{phox} deficiency and patients who have X-linked CGD with some residual enzyme activity overall tend to have milder disease that correlates with small but detectable levels of superoxide production.[1123,1145,1227] However, a severe clinical course can occur in some patients with variant X-linked CGD that is indistinguishable from what is observed in patients with complete absence of phagocyte superoxide production.[1228,1229] On the other hand, some individuals with undetectable levels of respiratory burst activity experience relatively few symptoms. Hence polymorphisms in oxygen-independent antimicrobial systems or other components regulating the innate immune response likely modify disease severity in CGD. Specific variants in the MPO, MBL, and FcγRIIa genes are associated with a higher risk for granulomatous or autoimmune/rheumatologic complications in CGD.[1230]

NADPH oxidase subunits, although most highly expressed in phagocytic leukocytes, are also found in other tissues, including endothelial and vascular smooth muscle cells, cardiomyocytes, β cells, and the brain, where they may function in the context of other related NADPH oxidases.[430,431,1231] This may explain an association of diabetes and cardiovascular disease with p47^{phox} deficiency.[1232]

Heterozygous carriers of the CGD trait are generally asymptomatic. Carriers of the AR forms of CGD are free from infection. Carriers of X-linked CGD, on the other had, typically have two populations of circulating neutrophils and monocytes: some with normal respiratory burst activity and others with none—in approximately equal numbers[1233-1239] because of random X-chromosome inactivation.[1240,1241] Up to 20% of female carriers of X-linked CGD are reported to have aphthous ulcers, discoid lupuslike skin lesions, and/or photosensivity.[1220,1242] Polyarthritis, arthralgia, and Raynaud phenomenon are also observed. Serologic testing for systemic lupus erythematosus is generally negative, as are immunofluorescence studies of biopsied lesions. Discoid lupuslike lesions are also occasionally reported in AR CGD patients.[1218,1219,1243] Because the lupuslike skin lesions typically do not appear to develop unless there is at least a subpopulation of nonfunctioning phagocytes, it has been hypothesized that autoantibodies to antigens from incompletely destroyed microbes may be responsible for the syndrome.[1220] Rarely, carriers of X-linked CGD have an unusually small percentage of oxidase-positive neutrophils, which if less than 10% to 15%, can result in infectious complications typical of CGD.[1159,1229,1233,1244]

Molecular Basis of CGD. CGD is classified according to the respiratory burst oxidase subunit that is affected (see Table 22-12 and Fig. 22-9). Also sometimes used is an abbreviated designation within each major genetic subgroup that includes the mode of inheritance and level of *phox* protein expression (see Table 22-12). In two large studies of 140 pedigrees in the United States and Europe, X-linked recessive defects in the gene for the gp91^{phox} subunit of flavocytochrome *b* accounted for approximately two thirds of cases, with the remainder resulting from AR inheritance of defects in genes encoding p47^{phox} (25%), p67^{phox} (5%), and p22^{phox} (5%).[1123,1132] However, deficiency of p47^{phox} accounts for only 7% of CGD in Japan.[1150] In regions where consanguineous marriage is common, the rate of AR CGD can exceed that of X-linked CGD.[1153]

Mutations in Flavocytochrome b. That CGD might result from a genetic defect in an electron-transporting cytochrome was first suspected based on reports that neutrophils obtained from the majority of patients with CGD lacked a low-potential cytochrome *b*.[1245-1247] It is now known that this corresponds to a flavocytochrome comprised of two subunits. One is a 91-kD glycoprotein, gp91^{phox}, encoded by the X-linked *CYBB* gene, which harbors both flavin and heme groups to function as the redox center of the NADPH oxidase. It is closely associated with a 22-kD polypeptide, p22^{phox}, with a corresponding *CYBA* gene that is affected in a subgroup of AR CGD. Formation of the gp91^{phox}/p22^{phox} heterodimer appears to be important for stable expression in phagocytes, and absent expression of both subunits is typically seen in both subgroups of CGD with flavocytochrome *b* mutations.[427,1248,1249]

The *CYBB* gene was mapped to Xp21.1 by its linkage to the X-linked form of CGD[1250] and was the first human gene to be cloned on the basis of its chromosomal location.[429] Defects in X-linked CGD are heterogenous[1150,1251-1253] and with a few exceptions are associated with absence of both the flavocytochrome heterodimer ($X91^0$) and respiratory burst activity. More than 600 distinct *CYBB* mutations have been identified in X-linked

CGD and are distributed across the gene. An international registry is accessible at http://bioinf.uta.fi.[930] In general, each mutation is unique to a given kindred. The findings indicate that the incidence of CGD represents many different mutational events without any founder effect, as expected for a formerly lethal disorder. Approximately 10% to 15% of X-linked CGD is caused by new germ line mutations.[1252]

A small percentage of patients with X-linked CGD express a small amount of residual flavocytochrome *b* (X91–) associated with low levels of superoxide production. Other rare patients have normal levels of a dysfunctional flavocytochrome *b* (X91+), involving mutations in gp91*phox* domains that either participate in oxidase assembly or are involved in its redox function.[1253,1254] Two unusual kindreds were recently reported in which there were point mutations in gp91*phox*, leading to marked reduction of flavocytochrome *b* expression and activity in macrophages compared to neutrophils.[1255] The mutations appeared to impair heterodimer formation with p22*phox*, which in neutrophils could be partially overcome by their higher levels of gp91*phox* expression relative to macrophages. Affected patients were susceptible to mycobacterial infections but did not suffer from other bacterial and fungal infections characteristic of CGD, highlighting the importance of macrophages for controlling mycobacteria.

Relatively large deletions in Xp21.1 involving CYBB and adjacent loci occur occasionally and are associated with complex phenotypes.[429,1250,1256-1259] These include CGD and McLeod syndrome (a mild hemolytic anemia with acanthocytosis that is associated with depressed levels of Kell antigens because of defects in the red cell antigen K_x), with or without concomitant Duchenne muscular dystrophy and retinitis pigmentosa. McLeod phenotype patients may develop anti-Kell antibodies when transfused with red blood cells, which can make future transfusion very difficult. These patients can also develop nerve and muscle disorders related to absent Kell expression in nonerythroid tissues.[1260-1262]

Aberrant regulation of gp91*phox* transcription has been identified in two unusual phenotypes and is associated with point mutations in the *CYBB* promoter near the transcription start site.[1263,1264] In one type, described in two unrelated kindreds, affected males have two distinct populations of neutrophils.[1228] One population, with normal gp91*phox* expression, accounted for 5% to 15% of circulating phagocytes and myeloid progenitor cells, whereas the other entirely lacked gp91*phox* expression. Affected males had a severe clinical course.[1228] Another unusual patient had neutrophils, monocytes, and B lymphocytes with markedly reduced levels of gp91*phox*, but gp91*phox* expression and function in circulating eosinophils was normal.[1265]

Mutations in the *CYBA* gene for the p22*phox* subunit of flavocytochrome *b* are an uncommon cause of AR CGD (see Table 22-12). The genetic defects are heterogeneous,[1266] and in most cases p22*phox* is not expressed (A22° CGD). In one patient, a proline to glutamine substitution in p22*phox* was associated with normal flavocytochrome *b* levels but a nonfunctional oxidase ($A22^+$ CGD).[1267] This mutation disrupted a cytoplasmic proline-rich domain of p22*phox* that otherwise binds to tandem src homology domain 3 (SH3) domains in p47*phox* during oxidase assembly.

Mutations in Cytosolic Subunits. Key in understanding the molecular components of the NADPH oxidase and subsequently unraveling the different genetic subgroups in CGD was the discovery that both the plasma membrane and the cytosol were required to reconstitute a catalytically active oxidase in a cell-free assay.[1268-1271] Complementation analysis using this assay identified two different subgroups of CGD in which the defect involved a cytosolic protein rather than the membrane-bound flavocytochrome *b*.[1272,1273] These proved to involve mutations in the neutrophil cytosolic factor 1 *(NCF1)* gene encoding p47*phox*, and in the *NCF2* gene for p67*phox* (see Table 22-12). The p47*phox* subunit functions as an adaptor protein important for efficient recruitment of cytosolic *phox* proteins to flavocytochrome *b* during NADPH oxidase assembly, whereas p67*phox* binds to gp91*phox* to activate electron transport.

In contrast to other forms of CGD, the most cases of p47*phox*-deficient CGD result from a single type of mutation, a GT deletion at the beginning of *NCF1* exon 2 that results in a frameshift and premature translational termination.[1266,1274,1275] Most patients are homozygous for this mutation without any history of consanguinity, although a few compound heterozygotes have been described with a missense mutation accompanying the GT deletion.[1276] The high frequency of the GT deletion reflects the fact that humans have closely linked pseudogenes for p47*phox* that contain the GT deletion.[1277,1278] Recombination or gene conversion events between the authentic *NCF1* gene and its pseudogene(s) lead to a nonfunctional *NCF1* allele containing the GT deletion.[1279] All reported patients with *NCF1* mutations do not express this protein (A47°). Perhaps because p47*phox* is an adaptor protein rather than directly involved in activating electron transport, A47° neutrophils can still generate very small amounts of superoxide, which may account for the overall milder course of this genetic subgroup.[1123,1145,1227]

Mutations identified in the *NCF2* gene for p67*phox* in patients with CGD are heterogeneous and typically result in absent p67*phox* expression (A67° CGD).[1266,1280-1284] In one patient where a triplet nucleotide deletion results in an in-frame deletion of lysine 58, a nonfunctional form of p67*phox* was expressed, which failed to translocate and was unable to bind to Rac.[1285]

Finally, the first patient with AR p40*phox* defects was recently reported, a compound heterozygote for two null *NCF4* alleles.[438,1286] The p40*phox* subunit plays a specialized role in regulating intracellular NADPH oxidase activity via its binding to phosphatidylinositol 3-phosphate. Although neutrophil NADPH oxidase activity on the plasma membrane was normal in this patient, phagosome oxidant production was profoundly impaired. The main clinical findings were granulomatous inflammation of the intestinal tract rather than the bacterial and fungal infections characteristic of other forms of CGD, perhaps reflecting the more selective role of p40*phox* and residual enzyme activity that may be sufficient for microbial killing.

Diagnosis. A diagnosis of CGD is suggested by the characteristic clinical features (Tables 22-13 and 22-14) or by a family history of the disease. Because the severity and onset of the disease can vary considerably among different patients, CGD should still be considered in adolescents and adults who have an unusual site of infection or carry an organism typical of CGD (see Table 22-13). The diagnosis of CGD is established by demonstrating an absent or greatly diminished neutrophil respiratory burst. It is important to have testing performed on appropriately handled blood samples and by experienced laboratories in order to avoid inconclusive or false normal results.

Many different methods have been used to monitor respiratory burst activity. One of the simplest and most accurate techniques is the nitroblue tetrazolium (NBT) slide test, in which neutrophils in freshly isolated blood are stimulated to undergo a respiratory burst in the presence of NBT.[1234,1235,1287,1288] When reduced by electrons donated from superoxide, the water-soluble yellow tetrazolium dye is converted into deep blue insoluble formazan deposits that precipitate on any cell that undergoes a respiratory burst. As shown in the NBT slide test in Figure 22-15, stimulated neutrophils and monocytes are normally strongly stained with NBT formazan deposits *(A),* whereas cells from a patient with classic X-linked CGD show compete absence of staining *(B).* Nearly 100% of normal cells are NBT-positive, in contrast to the mixed population of NBT-positive and NBT-negative cells seen in the patient's mother (see Fig. 22-15, *C*). In X91– CGD, characterized by a partial deficiency of flavocytochrome *b*, all neutrophils are weakly NBT-positive. Intermediate levels of NBT reduction are not seen in phagocytes of AR carriers. Flow cytometric assays of oxidase activity, such as those based on the conversion of dihydroxyrhodamine (DHR) 123 to rhodamine 123,[1289,1290] are increasing in use for diagnosis of CGD and like the NBT test provide both quantitative measurements of oxidant generation and the cell-by-cell distribution of activity (see Fig. 22-15, *D* to *G*). A small but measurable level of DHR fluorescence can be seen in A47° cells *(G),* which can also show weak staining in the NBT test, reflecting their small amount of residual oxidant production. The DHR assay is available in many referral centers and reference laboratories and can be performed on blood collected in heparin and stored overnight. Notably, neutrophils from patients with MPO deficiency can give a false-positive result for CGD in the DHR test because of weak DHR fluoresence.[1291] This is because although respiratory burst oxidase activity is normal, MPO is required to convert superoxide into the species that reacts with DHR.

Identification of the specific genetic subgroup for a patient with CGD is useful primarily for purposes of genetic counseling and prenatal diagnosis. There is also some clinical predictive value, because patients with p47^{phox} deficiency tend to have less frequent complications. With the exception of classic X-linked disease in a male whose mother is a carrier, determination of the affected gene (see Table 22-12) requires additional studies. Genetic testing for all subgroups of CGD is now available commercially. Other assays, available in research laboratories, include immunoblot analysis of *phox* protein expression in neutrophil extracts and flavocytochrome *b* spectroscopy. Testing for the McLeod red cell phenotype should be done if there is evidence of a large Xp21 deletion in patients with X-linked CGD.[1260] This can cause a mild hemolytic anemia as well as other complications (see "Mutations in Flavocytochrome b"). More importantly, there can be serious problems with development of hemolytic antibodies if these patients are transfused with Kell-positive blood.

Prognosis and Treatment. The prognosis for patients afflicted with CGD has continued to improve since the disorder was first described in the 1950s, at which time almost all patients died in childhood.[1127-1129] In one retrospective review of 38 patients studied between 1964 and 1989, actuarial analysis showed 50% survival through the third decade of life.[1292] In another retrospective study of 48 patients that took place between 1969 and 1985 in Paris, the actuarial survival rate was 50% at 10 years of age, with a prolonged plateau thereafter.[1143] Further refinements in management, the use of prophylactic antimicrobials and more active antifungal and antibacterial agents, and the introduction of IFN-γ therapy have continued to improve the prognosis for CGD.* There is a general consensus that a large majority of patients should survive well into their adult years. The overall mortality for all patients with CGD in the United States including adults was estimated to be 5% per year for X-linked CGD and 2% per year for AR CGD in a retrospective analysis from 2000.[1123] The most common causes of death were pneumonia and/or sepsis caused by the *Aspergillus* species of *B. cepacia*.[1123,1144] A more recent single institution study in 76 younger patients reported an overall mortality of 1.5% per year.[1294] As already noted, patients with deficiency of p47^{phox} typically exhibit a milder disease compared to those with flavocytochrome-negative CGD, likely because of small amounts of residual superoxide produced.[1123,1145,1227]

A multifaceted therapeutic approach is responsible for the greatly improved prognosis in CGD.[1143,1297,1298] The cornerstones of current management include: (1) prevention and early treatment of infections; (2) use of prophylactic antibacterial and antifungal therapy; (3) early use of parenteral antibiotics, including antifungal drugs, and augmented by surgical drainage or resection of recalcitrant abscesses; and (4) the use of prophylactic recombinant human IFN-γ (rIFN-γ).

Several approaches can be used to prevent infections. Patients with CGD should receive all routine immunizations (including live-virus vaccines) on schedule and an influenza vaccine yearly. Cuts and skin abrasions should be promptly cleansed with soap and water and rinsed with a solution of 2% hydrogen peroxide. The frequency and severity of rectal infections can be greatly reduced by avoiding constipation and soaking early lesions in warm, soapy water. Flossing and professional dental cleaning can help prevent gingivitis and periodontitis. The risk of

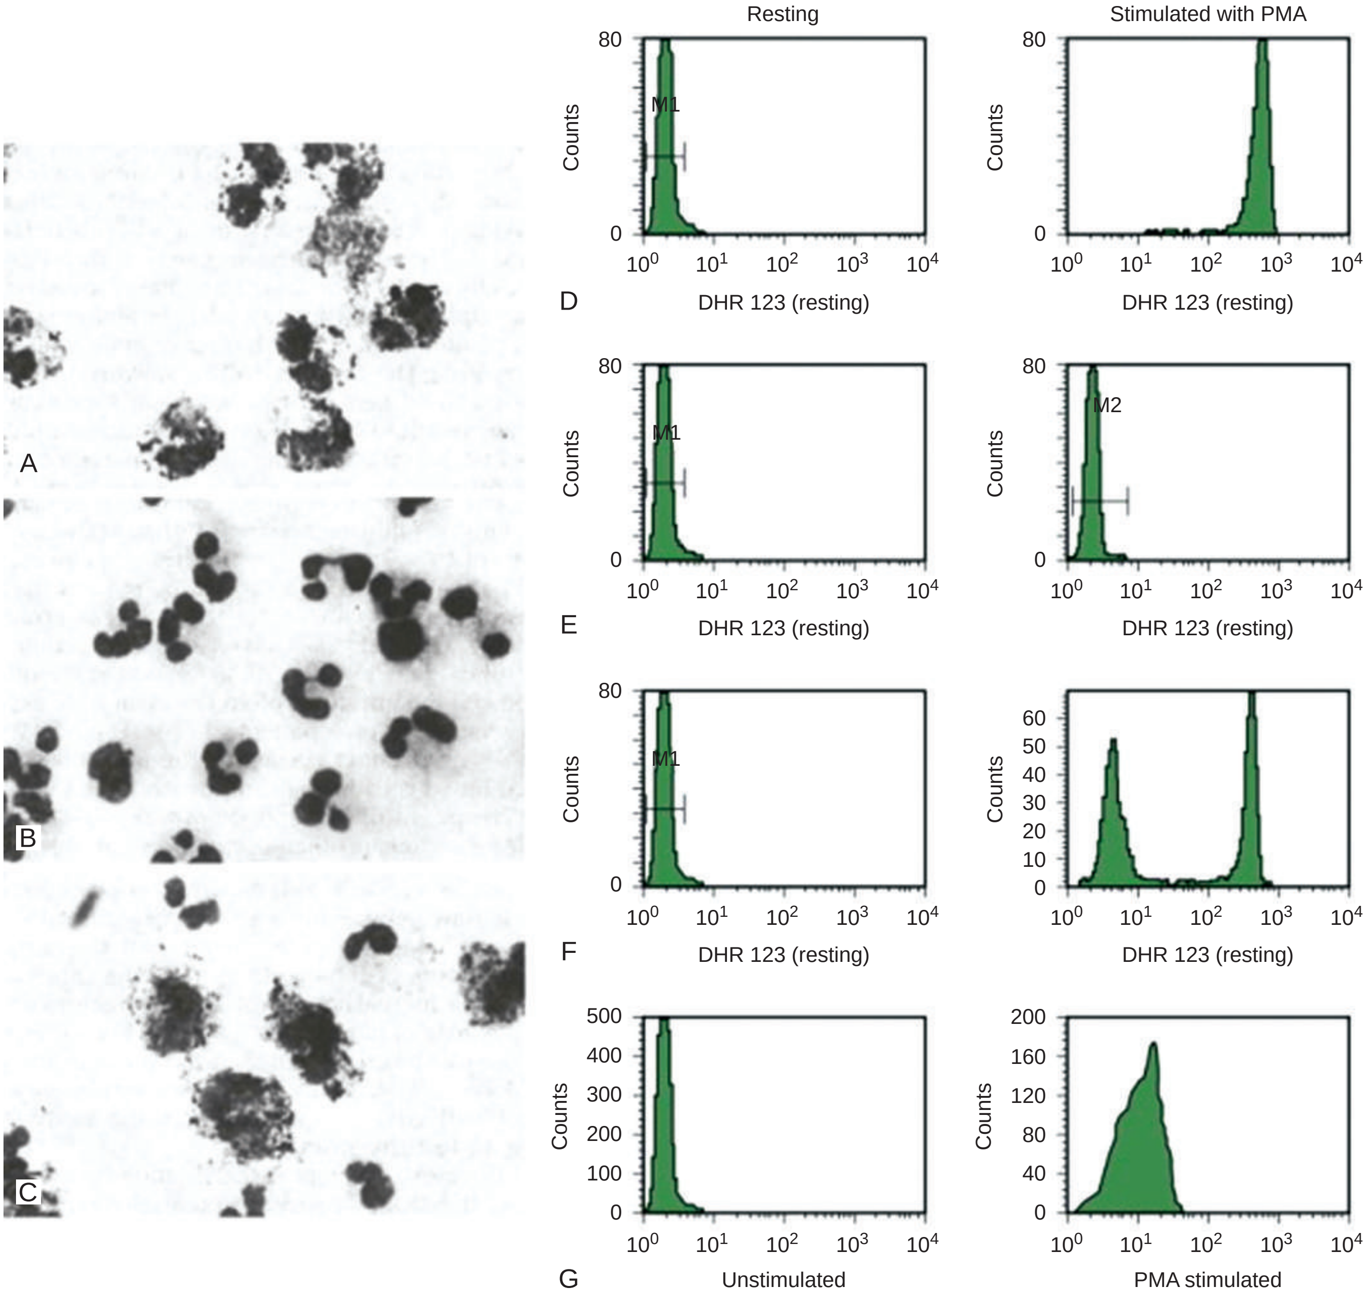

Figure 22-15 Analysis of neutrophil nicotinamide adenine dinucleotide phosphate oxidase activity for diagnosis of chronic granulomatous disease (CGD). **A-C**, Nitroblue tetrazolium (NBT) slide test. Peripheral blood neutrophils and monocytes from a drop of fresh whole blood were made adherent to glass slides and stimulated with phorbol myristate acetate *(PMA)*. **A**, Normal neutrophils and monocytes, all of which are NBT-positive. **B**, Neutrophils and monocytes from an X-linked patient with CGD, which are all NBT-negative. **C**, A mixture of NBT-positive and NBT-negative neutrophils from the X-linked carrier mother of the patient in part **B**. **D-G**, Dihydrorhodamine *(DHR)* 123 flow cytometry test. Nonfluorescent DHR 123 is taken up by neutrophils and becomes fluorescent after reaction with reactive oxygen species produced in the respiratory burst. **D**, Normal neutrophils. **E**, Neutrophils from an X-linked patient with CGD that do not fluoresce after stimulation. **F**, A mixture of nonfluorescent and fluorescent neutrophils from an X-linked CGD carrier. **G**, Neutrophils from a p47^{phox}-deficient patient, which show weak fluorescence after stimulation. *(Modified from Dinauer MC, Coates TD: Disorders of phagocyte function. In Hoffman R, et al, editors:* Hematology: basic principles and practice, *6th ed. Philadelphia, 2012, Saunders, p. 660.)*

Aspergillus infection can be decreased by avoiding marijuana smoke[1299] and decaying plant material (e.g., rotting wood, mulch, sawdust, hay), both of which often contain numerous *Aspergillus* spores.[1300,1301]

Prophylactic antibiotics for bacterial and fungal infections is an important component in the management of CGD. Retrospective studies showed that chronic prophylaxis with trimethoprim/sulfamethoxazole (5 mg/kg/day of trimethoprim given in one or two doses) can decrease the number of bacterial infections in patients with CGD without increasing rates of fungal infections or infections with pathogens resistant to trimethoprim/

sulfamethoxazole.[1143,1296] Dicloxacillin (25 to 50 mg/kg/day) can be used in patients with allergies to sulfa drugs, although there are relatively few data documenting its efficacy. Itraconazole is used for prophylaxis against fungal disease. A prospective study found an incidence of 3.4 *Aspergillus* infections (lung) per 100 patient years compared to 11.5 in a historical control group that did not receive any prophylaxis.[1302] A subsequent randomized, double-blind, placebo-controlled study further documented the efficacy of itraconazole for prophylaxis for fungal infections in CGD.[1295] Daily itraconazole is therefore now recommended for all patients with CGD (200 mg daily if 13 years of age or older or if weighing at least 50 kg, or 100 mg daily if less than 13 years of age or weighing less than 50 kg). Liver function tests should be monitored on patients receiving itraconazole.

rIFN-γ is another cornerstone of current management that reduces the frequency of serious infection in patients with CGD.[1294,1303-1305] The recommended dose of rIFN-γ in CGD is 0.05 mg (50 µg)/M^2 (or 0.0015 mg/kg if <0.05 M^2) given three times a week subcutaneously. A multicenter double-blinded, placebo-controlled phase III trial first established that rIFN-γ was an effective and well-tolerated agent for infection prophylaxis in CGD (Table 22-15).[1303] Patients receiving rIFN-γ had a 70% reduction in the number of serious infections during the study period. These beneficial effects were independent of age, mode of inheritance, and concomitant use of prophylactic antibiotics. The most common side effects were mild fever, headache and other flulike symptoms, which can be ameliorated with acetaminophen. No additional adverse effects, including any increased incidence of chronic inflammatory complications, have been noted with longer periods of prophylactic rIFN-γ (more than 10 years).[1294] On average, these patients are averaging one serious infection per patient every 4 to 5 years. rIFN-γ is used less often in Europe, where a retrospective study suggested no additional benefit over prophylactic antibiotics alone.[1147] However, longer follow-up study of the prospective trials does support a sustained benefit.[1294,1304,1305]

TABLE 22-15 Summary of the Phase III Study Establishing the Efficacy of Recombinant Interferon-γ for Infection Prophylaxis in Chronic Granulomatous Disease[*]

	Treatment Group		
Variable	**Interferon**	**Placebo**	**P Value**
Number of patients	63	65	
Patient years on study	52.1	50.9	
Age ± SD (yr)	14.3 ± 10.1	15.0 ± 9.6	
Number of patients with at least one serious infection	14 (22%)	30 (46%)	.0006
Serious infections per patient-year	0.38	1.1	
Total number of serious infections	20	56	<.0001
Number of hospital days per patient-year	8.6	28.2	
Percentage without Serious Infection[†]

The International Chronic Granulomatous Disease Cooperative Study Group. A controlled trial of interferon gamma to prevent infection in chronic granulomatous disease. N Engl J Med *324:509–516, 1991.*

SD, Standard deviation.

[*] The table shows a summary of the final results of a phase III randomized, double-blind, placebo-controlled study in which 128 patients with chronic granulomatous disease (GCD) received either recombinant interferon γ (50 mg/m^2 per dose) or placebo by subcutaneous injections three times per week for an average duration of 8.9 months (a controlled trial of interferon γ to prevent infection in CGD). The major endpoints of the study were time to the first serious infection and the number of such infections. A serious infection was defined as an event requiring hospitalization and parenteral antibiotics.

[†] The bottom portion of the table shows the Kaplan-Meier estimates of the cumulative proportion of patients free from serious infections for 12 months (after randomization) with adjustment for stratification factors.

The beneficial effect of rIFN-γ in most patients with CGD is not well understood. Since rIFN-γ increases levels of gp91^{phox} mRNA expression,[1306] increased superoxide production and bacterial killing can be seen in some patients with variant X-linked CGD (X91– in Table 22-12).[1306-1309] However, in most cases the effects of rIFN-γ are likely achieved by its enhancement of nonoxidative antimicrobial pathways and other phagocyte functions.

A common shortcoming in the treatment of patients with CGD is the failure to treat potentially serious infections promptly or long enough with the appropriate parenteral antibiotics. Patients who have CGD do not always have typical symptoms and signs even with serious infections, and fever and leukocytosis can be absent. An elevated sedimentation rate is often present, which can thus be very useful to monitor both as a clue to the presence of a significant infection as well as to observe the response to therapy. Therapy should be directed initially at characteristic pathogens. In the absence of a diagnostic culture, broad-spectrum gram-negative coverage, including for *B. cepacia*, should be administered in conjunction with a potent antistaphylococcal agent (e.g., a combination of nafcillin and ceftazidime). If the site of infection and/or offending pathogen are not known, and if the patient is severely ill and is not responding to the initial therapy within 24 to 48 hours, an aggressive search for the underlying infection should be conducted, including bronchoscopy or open biopsies, if indicated. In ill patients, therapy for fungi, *Nocardia* species, and *B. cepacia* may have to be given empirically.

B. cepacia is notorious for causing persistent fevers followed by bloodstream dissemination from the lung or other sites, resulting in sudden septic shock. *B. cepacia* generally responds to ceftazidime or meropenem,[1168] which are most effective if given before dissemination into the blood stream.

Proven or suspected fungal infections have been treated with amphotericin B in the past, although its use in many cases is being replaced with newer azole antifungal agents such as voriconazole or posaconazole.[1164,1167,1310-1312] Mortality from *A. fumigatus* is now uncommon.[1164] Fulminant "mulch" pneumonitis resulting from a large inhalation exposure to *Aspergillus* includes a substantial component of necrotizing inflammation and benefits from treatment with steroids in addition to antifungals.[1301] Nonfumigatus species of *Aspergillus* and some other fungal species remain difficult to treat, and early therapeutic surgery should be considered.[1164,1167,1313]

Even when appropriate antibiotics are used, infections often respond slowly, and generally should be treated with an antibiotic course that is more prolonged than for a patient with normal neutrophil function. Some infections may require many months of therapy, particularly *Aspergillus*, but with staphylococcal infections as well. Surgical drainage or resection can play a key role in the management of lymphadenitis, osteomyelitis, and abscesses of the liver, lungs, kidney, brain, and rectum. However, recent studies indicate that antibiotics combined with corticosteroids can be effective in curing liver abscesses without surgery.[1314,1315] Finally, granulocyte transfusions have been used in the setting of recalcitrant or life-threatening infections, but their efficacy is uncertain and pose a risk of alloimmunization.[1316]

Granulomatous inflammation in the esophagus, gastric antrum, and bladder can result in symptoms of obstruction, and in the bowel wall, a syndrome resembling inflammatory bowel disease. These complications can cause considerable morbidity in some patients with CGD, and are generally managed with a combination of antibiotics and steroids.[1200,1206,1294,1317-1319] Although the antiinflammatory effects of steroids are often beneficial in this setting even at low oral doses (1 mg/kg/day of prednisone),[1319] their use should be carefully monitored because of the additional immunosuppression associated with their use. TNF-blocking agents should be avoided in CGD as they are associated with a high risk of serious infections in these patients.[1320]

Allogeneic bone marrow transplantation can be used to successfully treat CGD.[1297,1321] Because of the risks associated with this procedure, marrow transplantation had been generally considered only for those patients who have frequent and severe infections despite aggressive medical management and also have a fully HLA-matched sibling donor. However, matched unrelated donors as well as reduced intensity conditioning regimens have now been successfully used in CGD, including several cases with ongoing fungal infections, although graft-versus-host disease can be a significant problem in adult patients.[1321-1324] Despite improved success rates and decreased complications with newer transplant regimens, which CGD patients should undergo transplantation remains an individualized decision, particularly for those with residual NADPH oxidase activity and little or no history of serious infection or other complications.

Gene replacement therapy for CGD using HSCs is under active investigation, and may be a future therapeutic modality.[1321,1325] Observations on carriers of X-linked CGD with skewed X-linked inactivation as well as preclinical studies in murine CGD suggest that partial correction of oxidase activity in as few as 10% of circulating neutrophils will have substantial clinical benefit.[1326-1329] In contrast to lymphocyte immunodeficiencies, there is no selective advantage for gene correction in CGD, and transplantation of gene-corrected cells must be combined with marrow conditioning both to reduce the number of uncorrected HSCs and to facilitate engraftment.[1325] Using a partially ablative conditioning regimen and a conventional γ-retroviral vector to treat three patients with X-linked CGD, 5% to 20% NADPH oxidase-positive neutrophils were detected in the first weeks after transplantation along with resolution of infections. However, 1% or fewer gene-corrected cells were seen over the long term.[1330] Results from another clinical trial, which used a γ-retroviral vector with a very potent viral long terminal repeat to drive expression of the X-linked CGD protein, illustrated the potential for adverse effects of gene therapy.[1331] In two patients reported, much higher numbers of oxidase-positive neutrophils (20% to 50%) were seen, along with resolution of chronic infectious complications. However, this high level of correction resulted from clonal expansion of myeloid precursors that harbored vector insertions in genes that are master regulators of myeloid cell growth, and led to the development of myelodysplasia and leukemia.[1321,1325,1331] Thus in addition to investigating conditioning regimens, current efforts for gene therapy of CGD are focused on evaluating vectors that lack strong enhancer sequences, which reduces the potential for insertional mutagenesis caused by activation of neighboring genes.[1321]

Glucose-6-Phosphate Dehydrogenase Deficiency

The substrate for the respiratory burst oxidase, NADPH, is generated by the first two reactions of the hexose monophosphate shunt, G6PD (see Fig. 22-7, reaction 8) and 6-phosphogluconate dehydrogenase. Since G6PD is the first enzyme in this pathway, its absence results in greatly diminished shunt activity and thus a decrease in the availability of NADPH. Thus severe G6PD deficiency in neutrophils results in an attenuated respiratory burst and, in some cases, a clinical picture somewhat similar to that observed in CGD.[1332-1335] The key features of G6PD deficiency are summarized in Box 22-16. The organisms causing infection in severely deficient patients are similar to those observed in CGD and are predominately catalase-positive bacteria.

In light of the relative high frequency of G6PD mutations in the African-American and Mediterranean populations,[1336] as well as the fact that leukocyte and erythrocyte G6PD are encoded by the same gene, it might be expected that clinically significant neutrophil G6PD deficiency would occur more often than it does

Box 22-16 Summary of Neutrophil Glucose-6-Phosphate Dehydrogenase Deficiency

Incidence	Extremely rare
Inheritance	X-linked
Molecular defect	Poorly characterized mutations that cause congenital nonspherocytic hemolytic anemia (CNSHA) in erythrocytes and functional failure of glucose-6-phosphate dehydrogenase (G6PD) in neutrophils (possibly kinetic mutants); other rare mutants may also be responsible
Pathogenesis	Severe functional failure of neutrophil G6PD (<5% of normal) leading to an extremely low steady-state concentration of reduced nicotinamide adenine dinucleotide phosphate (NADPH), which serves as the substrate for NADPH oxidase
Clinical manifestations	CNSHA (hemolytic anemia that occurs even in the absence of redox stress) Chronic granulomatous disease (CGD)-like syndrome with recurrent bacterial infections
Laboratory evaluation	Neutrophil G6PD activity <5% of normal Severely diminished respiratory burst Associated CNSHA with elevated reticulocyte count and diminished erythrocyte G6PD activity
Differential diagnosis	CGD Glutathione reductase or synthetase deficiency
Therapy	Prophylactic trimethoprim/sulfamethoxazole Aggressive use of parenteral antibiotics Transfusion support for severe anemia
Prognosis	Not clear because too few patients have been reported

From Curnutte JT: Disorders of phagocyte function. In Hoffman R, Benz EF, Shattil S, et al, editors: Hematology: basic principles and practice, *New York, 1991, Churchill Livingstone, p. 577.*

(fewer than 10 cases have been reported in the literature). One of the reasons it does not is that neutrophils must have a severe deficiency (less than 5% of normal G6PD levels) before respiratory burst function is adversely affected. Even low levels of G6PD are apparently sufficient to recycle NADP+ back to NADPH at a rate that permits reasonable levels of respiratory burst activity. Furthermore, studies on patients with variant CGD indicate that surprisingly low levels of respiratory burst activity (5% to 10% of normal) can still provide adequate protection against microbial infection (see “Chronic Granulomatous Disease”). Therefore clinically significant decreases in levels of neutrophil G6PD are rarely encountered. In most types of G6PD deficiency, neutrophil levels are in the range of 20% to 75% of normal.[1337,1338] Since most G6PD mutations cause the enzyme to decay over a period of days and weeks, levels in the short-lived neutrophil usually do not become critically low, even in some of the more unstable G6PD variants. Hence it appears that only a rare (and poorly understood) group of mutations causes extremely low levels of G6PD in neutrophils.

The diagnosis of G6PD deficiency should be considered in any patient with congenital nonspherocytic hemolytic anemia in whom the erythrocyte G6PD level is unusually low or the frequency of infections is high. The diagnosis is established by measuring the level of G6PD activity in neutrophil homogenates. Although not necessary for the diagnosis, neutrophil function tests show a diminished respiratory burst (5% to 30% of normal).[1334,1339] The treatment of neutrophil G6PD deficiency is similar to that of CGD except that the efficacy of rIFN-γ has not been demonstrated in the former. In general, G6PD deficiency appears to be somewhat milder than CGD, although recurrent pneumonias and a fatal infection with *C. violaceum* have been described.[1334,1339]

Myeloperoxidase Deficiency

MPO deficiency is the most common inherited disorder of phagocytes, although is rarely associated with clinical symptoms. Although only 17 known cases had been collected up to 1979, with the widespread use of automated flow cytochemistry in clinical hematology laboratories to enumerate peripheral blood neutrophils using peroxidase activity, it is now recognized to occur much more often. In the United States and Europe, complete deficiency is seen in approximately 1 in 4000 individuals, and partial deficiencies occur in 1 in 2000 people, although MPO deficiency occurs in only 1 in 57,000 people in Japan.[446,1340-1342] MPO deficiency is seen in neutrophils and monocytes. Peroxidase levels in eosinophils, on the other hand, are normal, because eosinophil peroxidase is encoded by a different gene.

MPO plays a pivotal role in amplifying the toxicity of H_2O_2 generated by the respiratory burst, and catalyzes the formation of HOCl from chloride and hydrogen peroxide (see Fig. 22-7, reaction 4).[423,446,1341] HOCl, in turn, reacts with a variety of primary and secondary amines to form chloramines, some of which can be toxic.[305] Moreover, HOCl is capable of activating latent metalloproteinases. Based on these considerations, one would expect that severe MPO deficiency should attenuate important antimicrobial reactions catalyzed by HOCl. MPO-deficient mice have impaired host defense against *Candida* and *Klebsiella*.[1343,1344] Neutrophils from patients with MPO deficiency show markedly abnormal in vitro killing of *C. albicans* and hyphal forms of *A. fumigatus*.[1341,1342] Curiously, however, these abnormalities are rarely reflected in an increased incidence of infection in patients except for rare individuals who also suffer from diabetes mellitus.[1340,1342] In these individuals, disseminated candidiases can be seen (Box 22-17). Several studies have suggested that MPO deficiency may also be associated with an increased susceptibility to malignancy.[1340,1345,1346]

Congenital MPO deficiency is inherited in an AR manner,[1341,1342] and variable expression of the defect is reported.[1346] The gene for MPO has been localized to

Box 22-17 **Summary of Myeloperoxidase Deficiency**

Incidence	1 in 2000 (partial deficiency) 1 in 4000 (total deficiency)
Inheritance	Autosomal recessive
Molecular defect	Myeloperoxidase (MPO) mutations affect posttranslational processing or heme incorporation
Pathogenesis	Partial or complete MPO deficiency leads to diminished production of hypochlorous acid (HOCl) and HOCl-derived chloramines; MPO products are necessary for rapid killing of microbes (especially *Candida*) but not absolutely required
Clinical manifestations	Usually clinically silent Rarely disseminated candidiasis/fungal disease (usually in conjunction with diabetes mellitus) May be increased risk of malignancy
Laboratory findings	Deficiency of neutrophil/monocyte peroxidase by histochemical analysis (eosinophil peroxidase normal) Delayed, but eventually normal killing of bacteria in vitro Failure to kill *C. albicans* and hyphal forms of *A. fumigatus* in vitro
Differential diagnosis	Acquired partial MPO deficiency seen in acute myelocytic leukemia (M2, M3, and M4), myelodysplastic syndromes, iron deficiency, or pregnancy
Therapy	None in asymptomatic patients Aggressive treatment of fungal infections when they occur Control of blood glucose levels in diabetes
Prognosis	Usually excellent

Modified from Curnutte JT: Disorders of phagocyte function. In Hoffman R, Benz EJ, Shattil S, et al, editors: Hematology: basic principles and practice. *New York, 1991, Churchill Livingstone, p. 578.*

the long arm of chromosome 17 at position q22-q23 near the breakpoint for the 15;17 translocation of promyelocytic leukemia.[1347,1348] The primary translation product is a 80-kD protein that undergoes cotranslational glycosylation and subsequent proteolytic cleavage to heavy and light chains, which oligomerize to form a tetramer composed of two heavy and two light chains.[1341] The molecular basis of congenital MPO deficiency reflects defects affecting MPO processing and heme incorporation. A variety of mutations have been reported.[1341] One common cause of complete absence of immunoreactive MPO is a point mutation that results in an arginine to tryptophan substitution at codon 569 (R569W).[1349,1350] The R569W mutation results in a maturation arrest of the MPO apoprotein, which fails to incorporate heme.[1351]

In addition to inherited MPO deficiency, secondary or acquired MPO deficiency can occur. MPO-deficient cells can be seen in the M2, M3, and M4 forms of acute myeloid leukemia as well as in approximately 25% of patients with MDS and chronic myeloid leukemia.[1352,1353] Other clinical situations in which secondary MPO deficiency can occur include pregnancy, iron deficiency, lead poisoning, ceroid lipofuscinosis, and Hodgkin disease.[1340] Attesting to a proinflammatory role for MPO, individuals deficient in MPO may have a decreased susceptibility to neutrophil-mediated vascular dysfunction.[446]

There are several possible reasons for the surprisingly mild clinical phenotype of MPO deficiency. First, neutrophils contain such a large amount of MPO that appreciable levels may be left in the cell even in cases of severe deficiency. These residual stores, coupled with normal levels of eosinophil peroxidase, may provide at least some degree of peroxidative activity at sites of infection. Second, the respiratory burst in MPO-deficient neutrophils is substantially augmented in terms of velocity and duration.[1354,1355] This may be because of the enhanced stability of the respiratory burst oxidase made possible by the absence of HOCl, which normally inactivates the oxidase.[1356] Finally, other oxidants produced by the respiratory burst may work together with the various granule antimicrobial proteins to provide sufficient protection against most microorganisms.[446]

Given the mild clinical nature of MPO deficiency, no treatment is generally required. Infections, when they occur, are treated as in normal individuals. It is important for the clinician to be aware of the increased risk of *Candida* infections in patients with MPO deficiency and to treat them aggressively when they do occur.

Disorders of Glutathione Metabolism

As shown in Figure 22-8 (reaction 6), glutathione peroxidase protects neutrophil proteins (including NADPH oxidase) from the harmful effects of H_2O_2 generated in the course of the respiratory burst by degrading it to water. The reducing equivalents for this reaction are carried by the reduced glutathione (GSH), the intracellular levels of which are maintained by recycling oxidized glutathione back to GSH by means of glutathione reductase (see Fig. 22-8, reaction 7). Glutathione levels are also maintained through de novo synthesis catalyzed by glutathione synthetase (see Fig. 22-8, reaction 9). Severe deficiencies of glutathione reductase and glutathione synthetase in neutrophils have been reported and found to cause moderately severe abnormalities in the respiratory burst.[1357-1361] The key features of each of these extremely rare disorders are summarized in Table 22-16.

Glutathione reductase deficiency has been reported in only a few families.[1362] In one, three siblings were found to have a marked deficiency of this enzyme in their neutrophils (10% to 15% of normal).[1357,1359] The inheritance appears to be AR, because the parents of the children were first cousins and their neutrophils contained 50% of the normal levels of glutathione reductase. The responsible mutation was a large deletion affecting the enzyme's dimerization domain.[1362] A second patient was a compound heterozygote for point mutations leading to a premature stop codon and a missense mutation affecting enzyme stability.[1362]

Clinically, none of the affected patients showed signs of increased infection. Their erythrocytes were also

TABLE 22-16 Disorders of Glutathione Metabolism

Disease Aspect	Glutathione Reductase Deficiency	Glutathione Synthetase Deficiency
Incidence	Several families	More than 50 families
Inheritance	Autosomal recessive	Autosomal recessive
Molecular defect	Diminished glutathione reductase levels in neutrophils (10%-15% of normal) and erythrocytes	Moderate to severe deficiency of glutathione synthetase activity
Pathogenesis	Brief respiratory burst truncated by toxic accumulation of H_2O_2 by glutathione	Same as with glutathione reductase deficiency except that the respiratory burst is normal; elevated 5-oxoproline levels because of lack of feedback inhibition by glutathione
Clinical manifestations	No history of repeated infection	Metabolic acidosis caused by elevated 5-oxoproline Otitis media Hemolysis with oxidant stress Intermittent neutropenia Hemolysis with oxidant stress Decrease in glutathione synthetase level
Laboratory evaluation	Glutathione reductase level diminished Premature cessation of O_2^- production by neutrophils	Normal respiratory burst
Differential diagnosis	Chronic granulomatous disease Glucose-6-phosphate dehydrogenase deficiency	Glutathione reductase deficiency
Therapy	None required	Vitamin E for hemolysis and infections Treatment of metabolic acidosis
Prognosis	Benign disorder	Relatively benign disorder

From Curnutte JT: Disorders of phagocyte function. In Hoffman R, Benz EJ, Shattil S, et al, editors: Hematology: basic principles and practice, *New York, 1991, Churchill Livingstone, p. 578.*
H_2O_2, Hydrogen peroxide; O_2^-, superoxide radical.

deficient in glutathione reductase and were prone to hemolysis in the face of oxidant stress. Two siblings suffered from juvenile cataracts and deafness. In vitro studies of neutrophil function were normal except for a premature termination of the respiratory burst after about 5 minutes.[1357] The probable reason for this defect is that NADPH oxidase is inactivated by the products of the MPO reaction.[1356] If glutathione reductase is deficient, the neutrophils cannot maintain a level of GSH sufficient to detoxify H_2O_2, leading to deactivation of the oxidase. One important insight gained from the study of these patients is that only a brief respiratory burst appears to be necessary for adequate microbial killing. The diagnosis of glutathione reductase deficiency is made by measuring the levels of this enzyme in neutrophil homogenates. No therapy is required, but avoiding foods and drugs containing potent oxidants will decrease the chance of depleting intracellular glutathione.

Several forms of congenital glutathione synthetase deficiency have been described, all of which are inherited in an AR fashion.[1363] Specific mutations have been reported. Only in those cases in which the glutathione synthetase activity is severely deficient in neutrophils (5% to 10% of normal) is a phagocytic abnormality detected.[1358,1360,1361] In contrast to glutathione reductase deficiency, neutrophils deficient in glutathione synthetase have a normal respiratory burst.[1358,1361] For reasons that are uncertain, in vitro bacterial killing is decreased. Despite this in vitro microbicidal defect, patients have only a relatively mild problem resolving infections. However, they suffer from a severe metabolic acidosis resulting from elevated levels of 5-oxoproline, a metabolite formed in one of the early steps in the pathway of glutathione synthesis, as well as progressive neurologic symptoms.[1363] This acidosis may be responsible for the intermittent neutropenia observed in patients with glutathione-synthetase deficiency.[1358] Because the erythrocytes in these patients are also deficient in glutathione synthetase, a hemolytic anemia brought on by oxidant stress is seen. Diagnostic tests include measurements of glutathione synthetase activity and glutathione levels in skin fibroblasts and red blood cells.[1363] Therapy with vitamin E and vitamin C has been found to be beneficial in patients who suffer from hemolysis and infection.[1358,1363]

Glutathione peroxidase (see Fig. 22-8, reaction 6) was found to be decreased to levels 25% of normal in three unrelated patients with a clinical syndrome resembling CGD.[1364,1365] While this enzyme plays an important role in removing H_2O_2, it has not been established whether the degree of deficiency seen in these patients is sufficient to cause functional abnormalities in neutrophils. Two of the affected kindreds were subsequently shown to have a severe deficiency of the respiratory burst oxidase flavocytochrome *b*.[1244] Thus it appears that in at least two of these previously reported cases, CGD is the underlying problem, not glutathione peroxidase deficiency.

Disorders of Cytokines and Impaired Phagocyte Function

Inherited defects in the production and response to inflammatory cytokines by phagocytes or other cells of the immune system can present with recurrent or unusual bacterial and fungal infections (see Chapter 24).[65,1366-1370] All of these disorders are rare. In addition to the disorders described, HIES is also caused by defects in cytokine signaling, as discussed earlier in this chapter.

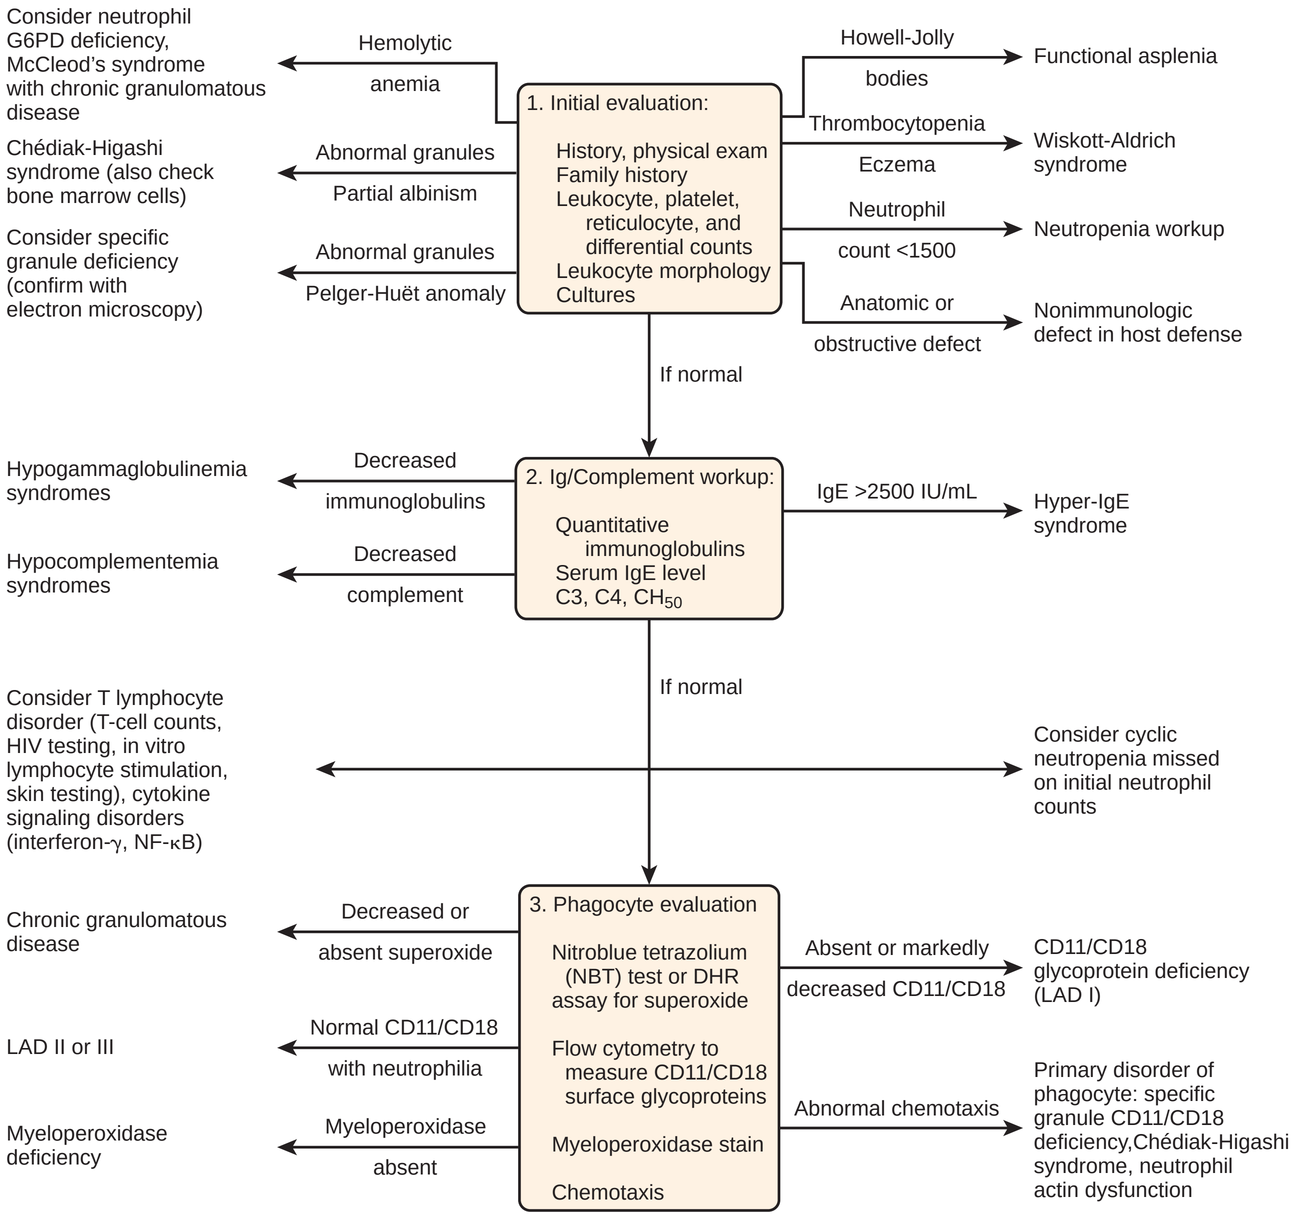
Defects in a group of genes regulating the production and macrophage response to IFNγ are associated with recurrent and severe atypical mycobacterial infections, as well as salmonellae and viral infections in some subgroups.[1369,1371-1373] The phenotype of this group of disorders is also referred to as Mendelian susceptibility to mycobacterial diseases (MSMD). The distinctive and limited spectrum of infections in affected patients results from defects in the IFNγ pathway. IFNγ is secreted by NK and T cells in response to IL-12 and IL-23 released by macrophages and dendritic cells. Some patients have AR mutations in the p40 subunit of the IL-12 and IL-23 cytokines, leading to their decreased expression; another subgroup of patients have mutations in the β_1 subunit of the receptor for IL-12 and IL-23; in both of these groups, levels of IFNγ are abnormally low. Other patients have either AR mutations affecting the IFNγ receptor, leading either to loss of receptor expression or complete or partial loss of IFNγ binding. Dominant IFNγ receptor mutations leading to partial IFNγ receptor deficiency are also described. The phenotype is milder in patients with partial defects. Very rarely, patients have partial or complete deficiency in the STAT-1 protein that is critical for transduction of IFNγ-mediated signals. Mutations in the *CYBB* gene that selectively impair gp91^{phox} expression and NADPH oxidase activity in macrophages but not neutrophils are also a cause of X-linked MSMD.[1255]

Defects in IL-17–mediated signaling are associated with susceptibility to chronic mucocutaneous candidiasis (CMC) and perhaps cutaneous *Staphylococcus* infections. These include dominant-negative mutations in *STAT3* associated with AD HIES and recessive or dominant-negative mutations involving the IL-17 receptor.[1370] Recessive mutations in the caspase recruitment domain-containing protein 9 (*CARD9*) impair intracellular signaling responses downstream of C-type lectin receptors for fungal cell walls that are necessary to generate TH17 responses to *Candida*. Affected patients can develop CMC as well as systemic candidiasis and also have problems with control of dermatophytes.[1370,1374] Interestingly, human neutrophils have impaired killing of *Candida* but not of *Aspergillus* or bacteria, associated with abnormal phagolysosome structures but normal NADPH oxidase activity.[1375]

Recurrent pyogenic infections are characteristic of a group of genetic disorders involving the NF-κB signaling pathway. These include patients with AR mutations in IL-1 receptor–associated kinase (IRAK) 4, a kinase in the toll and IL-1 receptor signaling pathway.[1369,1376,1377] Affected children have recurrent and sometimes fatal infections with *S. pneumoniae* and *S. aureus*, along with low or absent fever and inflammatory responses. Patients with anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) syndrome have either X-linked recessive mutations in the gene encoding NEMO, a regulatory protein that activates NF-κB, or, much less commonly, an AD defect in IκBA, and NF-κB inhibitor. In addition to widely spaced abnormal teeth, hypohidrosis, and hypotrichosis, children affected with EDA-ID have recurrent pyogenic infections with a minimal system inflammatory response, and can also develop opportunistic infections with atypical mycobacteria, viruses, or *Pneumocystis carinii*.

Evaluation of the Patient with Recurrent Infections

The patient who has recurrent infections can be a diagnostic challenge. Many of the phagocyte disorders present with similar clinical manifestations that can overlap those seen in inherited or acquired disorders of lymphocyte function. Furthermore, the majority of patients with recurrent infections do not have an identifiable granulocyte or monocyte defect. Given this low yield and the lack of ability to characterize many aspects of phagocyte function in routine laboratory studies, physicians are faced with the difficult question of which patients merit a complete evaluation. Those who have at least one of the following clinical features are more likely to have a phagocyte defect: (1) an unusually high frequency of bacterial and fungal infections; (2) the presence of an infection at an unusual site (e.g., a hepatic or brain abscess); (3) infections with atypical pathogens (e.g., *Aspergillus* pneumonia, disseminated candidiasis, lymphadenitis resulting from *Serratia* or *Klebsiella,* disseminated mycobacterial infection); (4) infections of exceptional severity; and (5) childhood periodontal disease. Certain other clinical findings can also be helpful. For example, a child with nystagmus, fair skin, and recurrent staphylococcal infections should be evaluated for CHS, whereas an infant with neutrophilia, bacterial infections, and delayed separation of the umbilical cord should be tested for LAD. Once the physician has decided that a phagocyte evaluation is warranted, the algorithm present in Figure 22-16 may be helpful in organizing the work-up. When coupled with a thorough clinical history and physical examination, the laboratory tests outlined in Figure 22-16 should help the physician to establish the diagnosis and formulate an appropriate therapeutic plan. With the advent of cost-effective genome and exome sequencing, it is also anticipated that new inherited disorders of phagocyte function will be defined in the coming years.[1378]



1. Initial evaluation:
History, physical exam
Family history
Leukocyte, platelet, reticulocyte, and differential counts
Leukocyte morphology
Cultures
Hemolytic anemia
Consider neutrophil G6PD deficiency, McCleod's syndrome with chronic granulomatous disease
Abnormal granules
Partial albinism
Chédiak-Higashi syndrome (also check bone marrow cells)
Abnormal granules
Pelger-Huët anomaly
Consider specific granule deficiency (confirm with electron microscopy)
Howell-Jolly bodies
Functional asplenia
Thrombocytopenia
Eczema
Wiskott-Aldrich syndrome
Neutrophil count <1500
Neutropenia workup
Anatomic or obstructive defect
Nonimmunologic defect in host defense
If normal
2. Ig/Complement workup:
Quantitative immunoglobulins
Serum IgE level
C3, C4, CH50
Decreased immunoglobulins
Hypogammaglobulinemia syndromes
Decreased complement
Hypocomplementemia syndromes
IgE >2500 IU/mL
Hyper-IgE syndrome
If normal
Consider T lymphocyte disorder (T-cell counts, HIV testing, in vitro lymphocyte stimulation, skin testing), cytokine signaling disorders (interferon-γ, NF-κB)
Consider cyclic neutropenia missed on initial neutrophil counts
3. Phagocyte evaluation
Nitroblue tetrazolium (NBT) test or DHR assay for superoxide
Flow cytometry to measure CD11/CD18 surface glycoproteins
Myeloperoxidase stain
Chemotaxis
Decreased or absent superoxide
Chronic granulomatous disease
Normal CD11/CD18 with neutrophilia
LAD II or III
Myeloperoxidase absent
Myeloperoxidase deficiency
Absent or markedly decreased CD11/CD18
CD11/CD18 glycoprotein deficiency (LAD I)
Abnormal chemotaxis
Primary disorder of phagocyte: specific granule CD11/CD18 deficiency,Chédiak-Higashi syndrome, neutrophil actin dysfunction

Figure 22-16 Algorithm for the workup of a patient with recurrent infections. The various tests are described in the appropriate sections of the chapter. Units for the neutrophil count *(box 1)* are neutrophils/mm^3. *DHR,* Dihydrorhodamine; *G6PD,* glucose-6-phosphate dehydrogenase; *HIV,* human immunodeficiency virus; *Ig,* immunoglobulin; *LAD,* leukocyte adhesion deficiency; *NBT,* nitroblue tetrazolium; *NF-κB,* nuclear factor κB. *(Modified from Lehrer RI, Ganz T, Selsted ME, et al: Neutrophils and host defense.* Ann Intern Med *109:127–142, 1988.)*

Helper T-Cell Differentiation and Function
Cytotoxic T-Cell Differentiation and Function
Control of the Immune Response: Regulation and Termination of T-Cell Activation
NONCONVENTIONAL T-CELL SUBTYPES
Development and Function of CD1-Restricted T Cells or Invariant Natural Killer T Cells
DEVELOPMENT AND FUNCTION OF T-Cell Receptor γδ T CELLS
NATURAL KILLER CELL DEVELOPMENT AND FUNCTION
CONCLUSIONS

The immune system is a complex network of cells that serve to discriminate "self" from "nonself"—that is, to recognize one cell as one's own and another cell as foreign or infected. This capacity helps protect the organism from infection by foreign pathogens (bacteria, viruses, and parasites) and from malignant degeneration. In addition, the cells involved in the immune response mediate rejection of foreign allografts. Although immune cells recognize and respond to all manner of foreign elements, at the same time they must not respond inappropriately to self-antigen. Education of immune cells results in a state of immunologic tolerance—that is, the absence of destructive antiself immune responses. Failure of self versus nonself discrimination, or failure of immunologic tolerance, may result in autoimmunity.

Whereas collectively a number of different kinds of cells are involved in the response to infection, the cells involved in mediating adaptive immunity are lymphocytes (Table 23-1). The adaptive immune response is broadly classified into two categories: (1) humoral immunity, mediated by antibodies produced by B lymphocytes and their progeny; and (2) cell-mediated immunity, dependent

TABLE 23-1 Innate Versus Acquired Immunity

	Innate Immunity	Acquired Immunity
Specificity	Nonself	Random (in the context of self)
Effector cell type	Polymorphonuclear leukocytes (PMNs, neutrophils), natural killer cells, macrophages, eosinophils, etc.	Lymphocytes: B and T cells
Cell surface receptors	Germline	Rearranged
Distribution	Nonclonal	Clonal
Kinetics of the initial response	Rapid and immediate	Slow

on cell-cell interactions and mediated by T lymphocytes. Both T and B lymphocytes are derived from early hematopoietic stem cells (HSCs) and are distinguished not by morphology but by rearrangement of their antigen-specific receptors, by function, and by the expression of different cell surface molecules. In addition to adaptive immunity, natural or innate immune mechanisms also work to defend an individual from pathogens (see Table 23-1). Natural killer (NK) cells, also derived from bone marrow progenitors, serve as principal components of innate immunity and are discussed briefly later in this chapter. In addition, polymorphonuclear leukocytes (neutrophils), eosinophils, macrophages, and other myeloid cells are important components of the body's early defense against microorganisms and are discussed in Chapter 22.

The acquired or adaptive immune response is mediated in large part by the recognition of a variety of cell surface proteins encoded by genes of the major histocompatibility complex (MHC). The MHC, located in the human genome on the short arm of chromosome 6, encodes two classes of proteins, MHC class I and MHC class II, that are highly polymorphic within the population and involved in the immune response. In humans these genes are termed *human leukocyte antigens* (HLA class I and HLA class II), as defined further later. In addition to HLA determinants, the MHC also encodes several secreted proteins of the complement system, selected immune modulators such as tumor necrosis factor (TNF), and specific proteins required for proper processing of antigen.

In addition to self-nonself discrimination, the adaptive immune response is further characterized by immunologic specificity and by memory. Acquired resistance to one antigen does not confer resistance to another unrelated (non–cross-reactive) antigen. The immune response must be capable of eliminating a foreign pathogen and developing mechanisms so that a second exposure to the same agent results not in worse disease but in more rapid elimination of the foreign agent. Cells previously exposed to and specific for one foreign protein or antigen respond more rapidly and more effectively to subsequent exposure to that same antigen, thereby leading to an anamnestic or secondary immune response. The immune response is highly regulated; cooperativity among different cellular elements and between cells and soluble mediators leads to modulation (i.e., amplification or suppression) of the immune response.

Technical advances, including single-cell cloning, monoclonal antibody production, generation of transgenic and knockout animals, and sequencing of the genome, have led to a veritable explosion in the number of cell surface proteins, cytokines, and chemokines discovered. The nomenclature has evolved and can be confusing. Cell surface proteins are often named by a cluster of differentiation (CD) assignment; the website http://www.uniprot.org/docs/cdlist contains links to protein information listed by CD name. Interleukins, the name given to soluble factors secreted by leukocytes or that act on leukocytes, or both, can be found along with their receptors at this site of the Human Gene Nomenclature Committee: http://www.genenames.org/genefamily/il.php. This chapter will focus on specific or acquired immunity and principally on the differentiation and function of B and T lymphocytes.

LYMPHOCYTE DEVELOPMENT

All B cells, T cells, and NK cells derive from pluripotent HSCs that arise first in fetal liver and then postnatally in the bone marrow. HSCs differentiate in the bone marrow and migrate to the appropriate lymphoid organs. These HSCs express cell surface CD34, a heavily glycosylated protein of 105 to 120 kd.[1] Although CD34 serves as a marker for hematopoietic progenitors, its expression is not limited to these cells alone. CD34 is also expressed on early lymphoid (but not pluripotent) progenitors, endothelial cells in small vessels, some embryonic fibroblasts, and some cells in the nervous system.[2] CD34 may be involved in cell-cell adhesion[3] and may be important for inhibition of hematopoietic differentiation.[4] CD34+ hematopoietic precursors give rise to both myeloid and lymphoid early progenitors. The traditional paradigm makes a strong distinction between HSC contained within the CD34+ compartment and lineage committed progenitors, which lack long-term reconstitution potential. Early myeloid differentiation derives from common myeloid progenitors (CMPs), which can give rise to common granulocyte-monocyte precursors (GMPs) or megakaryocyte-erythroid precursors (MEPs). The common lymphoid progenitor (CLP) differentiates into cells of the T (and NK) and B lineage. Dendritic cells can be generated in vitro from CD34+ bone marrow cells exposed to certain cytokines, but the relevant in vivo precursor population remains controversial,[5] and CLP, CMP, and GMP are all shown to contain dendritic cell potential.[5,6,7,8] New evidence from murine studies suggests that in single cell transplants, individual cells defined as HSC can give rise after a single division to one long-term repopulating cell and one myeloid committed cell[9]; thus lineage commitment may occur in individual cells at the HSC stage. How this translates to the human situation has yet to be uncovered. T-lymphocyte differentiation occurs largely in the thymus and is discussed in detail later. B-cell maturation occurs in the bone marrow and peripheral lymphoid organs.

Naïve B and T cells released into the peripheral blood have exquisite specificity. These resting B and T cells circulate in a quiescent state and function only after encountering cognate antigen (i.e., the specific substance that the lymphocyte recognizes). Recognition of antigen alone is generally insufficient to trigger lymphocyte activation; both B and T cells require other so-called *costimulatory signals*, in the form of cell surface receptor engagement or soluble factors, for effector function. Recognition of antigen by T cells and the costimulatory signals for both B and T cells are typically mediated by accessory cells of the innate immune system called *antigen-presenting cells* (APCs). Lymphocytes activated by specific antigen in the appropriate costimulatory context proliferate and mature into effector cells, a portion of which eventually differentiate into long-lived memory cells. The specifics of peripheral maturation, costimulation, and function of B and T cells are detailed in later sections.

LYMPHOCYTE SPECIFICITY

Immunologic specificity is conferred by antigen-specific receptors expressed on the surface of B and T lymphocytes and by specific antibodies (immunoglobulins [Igs]) secreted by B cells and plasma cells (Fig. 23-1). An individual lymphocyte has only one specific antigen to which it can respond. Each T cell expresses a unique T-cell receptor (TCR) and each B cell a unique Ig that can either be displayed on the surface (B-cell receptor [BCR]) or be secreted. The membrane BCR and secreted Ig of the B cell interact with epitopes expressed by native antigens, largely protein and nonprotein antigens such as complex epitopes of glycoproteins, lipids, and nucleic acids. Unlike Ig, the TCR recognizes small (most commonly 9 to 11 amino acid long) processed oligopeptides bound within the cleft of an MHC molecule on the surface of an APC. Dendritic cells, B cells, monocytes-macrophages, epithelial Langerhans cells, and (in humans) endothelial cells function efficiently as APCs. These APCs bear costimulatory molecules on their cell surface (discussed later), secrete cytokines, and process antigen; it is the complex formed between the processed peptide fragment of antigen and MHC proteins that interacts with the TCR. Exposure to antigen induces activation of only lymphocytes that bear Ig receptors or TCRs specific for that antigen. Any individual, however, has approximately 10^7 to 10^9 different T-cell and B-cell specificities. It is this clonal variability and diversity of the lymphocyte repertoire that maintain effective protection against foreign invasion.

B-CELL ONTOGENY

The first phase of B-cell maturation occurs in the bone marrow, where HSCs committed to B-lymphoid lineage develop into immature IgM+ IgD– B cells. The immature B cells exit the bone marrow, circulate in peripheral tissues, and mature further (Fig. 23-2). The most critical steps in B-cell development at this stage involve the expression of Ig molecules on the surface as BCR, whose specificity is the same as the antibody that will ultimately be secreted by activated mature B-cell progeny. The diversity of the B-cell repertoire is due in large part to random rearrangement of multiple germline genes for Ig that are spliced to encode a unique Ig molecule for each cell. Highly regulated checkpoints ensure that only B cells that successfully rearrange Ig genes are selected for survival.[10-12]

	B lymphocyte	T lymphocyte
Antigen-specific receptor	Surface immunoglobulin (IgM, IgD)	T cell receptor (αβ or γδ)
Surface signaling molecules	Ig-α, Ig-β	CD3, ζ family
Surface molecules	CD19, CD22, FcR	CD4, CD8, CD2, CD28
Principal site of development	Bone marrow	Thymus
Effector function	Humoral immunity: antibody secretion	Cell-mediated immunity: cytokine production, cytolysis regulatory role

Figure 23-1 Characteristics of B and T lymphocytes. Both B and T lymphocytes have rearranged immune system receptors. Immunoglobulin (Ig) molecules are expressed on the surface of cells, whereas T cells are characterized by expression of the clonotypic T-cell receptor complexed to CD3 chains. Other important differences are listed.

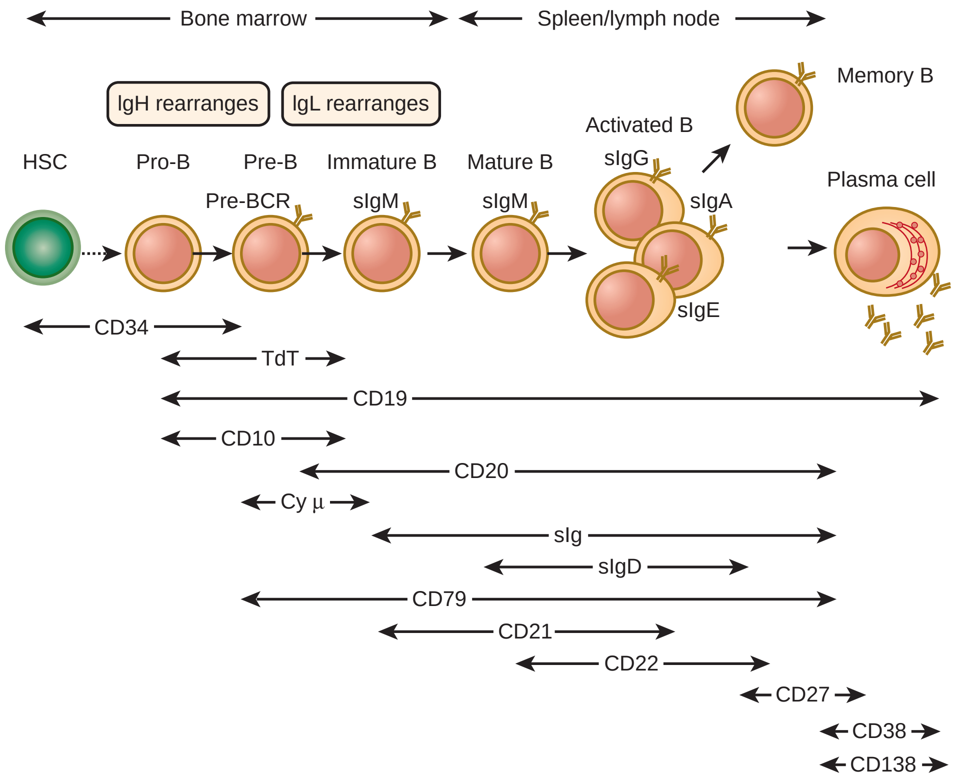

Figure 23-2 Overview of B-cell development. Pro-B cells develop from pluripotent hematopoietic stem cells (HSC) in bone marrow and acquire cell surface markers such as the pan-B-cell marker CD19, CD10, and terminal deoxynucleotidyl transferase (TdT). Serial rearrangement of the heavy- and light-chain loci drives expression of first the pre–B-cell receptor (pre-BCR) and later the B-cell receptor or surface IgM (sIgM). Downregulation of early markers at the pre-B stage gives way to expression of markers of immature and mature B cells, such as CD20, CD21, and CD22. Activation of the B cell with appropriate T-cell help leads to isotype switching and the expression of either IgA, IgG, or IgE. Switched B cells that form memory cells are characterized by expression of CD27 and downregulation of IgD, whereas activated B cells that proceed to the plasma cell stage lose most B-cell markers, upregulate CD38 and CD138, and secrete high levels of soluble specific antibody.

Elimination of B cells whose receptors have high affinity for self-antigens is important to prevent autoreactivity. Finally, immature B cells released from the bone marrow complete their development in the spleen and differentiate into at least two distinct lineages of mature naïve B cells: follicular B cells and marginal-zone B cells.

Immunoglobulin Structure

The structures of antibody molecules all share remarkable conservation of secondary conformation. The Ig-like fold is a domain shared among diverse proteins, each with signature hydrophobic common cores and common disulfide bridges. The antibody molecule is the prototype member of the Ig supergene family, a group that includes not only Ig but also TCR, the MHC, and a number of costimulatory molecules. Each Ig molecule is composed of two light chains of approximately 25 kd and two heavy chains of approximately 50 or 70 kd (Fig. 23-3); each chain is composed of multiple Ig domains. B-cell antibodies can be subdivided by heavy-chain isotype and further subdivided by subclass (Table 22-2).

There are five classes of antibodies—IgM, IgG, IgA, IgD, and IgE—defined by expression of the heavy chain: μ, γ, α, δ, and ε. The Ig-heavy chains contain sites for binding of Fc receptor (FcR) and complement, and each subtype appears to have a particular role in immune defense. The first class of antibody to be produced during development is IgM, which is expressed on the surface as a monomer and secreted as a pentamer. B cells that have undergone class switching (discussed later) express IgG, IgA, IgD, or IgE on the surface as the BCR or secrete a splice form of the Ig with the same heavy-chain isotype and specificity but lacking a transmembrane region (or both). The function of IgD in humans is not clear, although its expression is a marker for later B-cell development. IgA is secreted as a dimer and is found at mucosal surfaces such as the intestine. The bulk of circulating Ig is in the form of IgG, which is monomeric and further subdivided into four subclasses: IgG1, IgG2, IgG3, and IgG4. Persistently low serum levels of one or more IgG subclasses,[13,14] in the presence or absence of IgA deficiency,[15] may cause individuals to be susceptible to recurrent infections.[16] Though controversial, prophylactic use of intravenous Ig has been suggested.[17,18]

There are two subclasses of light chains: κ and λ (see Fig. 23-3). Both subclasses appear to serve similar functions. Monoclonal disorders of terminally differentiated mature B cells or plasma cells (e.g., multiple myeloma) express cells of a given light chain—that is, either κ or λ, but not both.

The structure of each Ig molecule is determined by hydrophobic interactions and disulfide bridges between

Figure 23-3 Diagrammatic representation of the immunoglobulin (Ig) molecule. The Ig molecule has two light chains of approximately 25 kd, each with two Ig domains (C_L and V_L), and two heavy chains of 50 to 70 kd, each composed of four Ig domains (C_H1, C_H2, C_H3, and V_H). The antigen binding region is defined by the variable regions of the heavy and light chains (V_H and V_L). There are five subclasses of the heavy chain: IgG, IgA, IgM, IgD, and IgE.

the two heavy chains and two light chains (see Fig. 23-3). For each chain the N-terminal domain has a variable or polymorphic amino acid structure (V_H for heavy chain, V_L for light chain), whereas the C-terminal portions are constant within each heavy-chain or light-chain class (termed C_H1, C_H2, C_H3 for heavy chain and C_L for light chain). These domains form pairs, V_H with V_L, C_H1 with C_L, and C_H3 with C_H3. Proteolytic digestion of Ig by papain results in two Fab fragments, each composed of the V_H/V_L, C_H1/C_L domains, and an Fc fragment composed of the two C_H2 and two C_H3 domains. The binding region of Ig that recognizes antigen is composed of portions of the V_H and V_L domains. Within each variable region there are three portions with increased amino acid variation, called *hypervariable regions* (HV1, HV2, HV3) or complementarity-determining regions (CDR1, CDR2, CDR3). The highest variability is found in CDR3, and all three CDRs from both chains participate in the binding of antigen. Variability within each variable region and each CDR and pairing of a unique heavy chain with a unique light chain all contribute to the combinatorial diversity of Ig specificity.

Immunoglobulin Rearrangement and B-Cell Maturation in Bone Marrow

The genes encoding the heavy chains of Ig are located on human chromosome 14, whereas the genes encoding κ and λ light chains are located on chromosomes 2 and 22, respectively. The heavy- and light-chain loci are each composed of variable (V), diversity (D), and joining (J) gene segments that recombine to yield the V_H and V_L domains, which in turn form the antigen contact surface of the antibody molecule and confer specificity. In addition, the heavy-chain locus contains nine heavy-chain constant (C) region genes (μ, δ, γ1, γ2, γ3, γ4, α1, α2, and ε constant regions) that define the mature Ig isotype.

Ig rearrangement occurs serially, and cells failing to rearrange the Ig genes successfully are eliminated and do not develop further (Fig. 23-4). B-cell maturation also results in cell surface protein expression patterns that are used to define the pro–B-cell, pre–B-cell, and immature B-cell stages of development. CD34+ CD19– CD10– progenitors that have not yet committed to the B lineage have Ig genes in the germline configuration. The earliest B-cell precursors express the pan B-cell marker CD19 and the early marker CD10. They also express components of the rearrangement machinery such as recombination-activating genes (RAGs) and thus have early gene rearrangements detectable. Rearrangement begins with one heavy-chain allele; one of the 29 D_H exons is spliced to one of the 6 J_H exons, the intervening D and J sequences are eliminated, and a DJ segment is produced. The pro-B cell then splices one of the approximately 50 V_H exons to the DJ segment to form a V(D)J segment. Finally, the μ constant region of the heavy chain (C_μ) is spliced onto the V(D)J segments.

Differentiation to the pre-B stage is triggered by expression of intact μ heavy-chain protein or cytoplasmic μ, which occurs only in cells that bear in-frame productive V(D)J-C_μ rearrangements. If rearrangement of the first heavy-chain locus is unsuccessful, the second allele undergoes rearrangement. Because the light-chain genes have not yet been expressed, cytoplasmic μ complexes instead with the nonpolymorphic surrogate light-chain proteins λ5 and VpreB. Cytoplasmic μ, surrogate light chain, and the accessory signaling molecules Ig-α (CD79a) and Ig-β (CD79b) together form the pre–B-cell receptor. Ensuing signals induce proliferation and instruct the cell to begin rearrangement of one of the κ

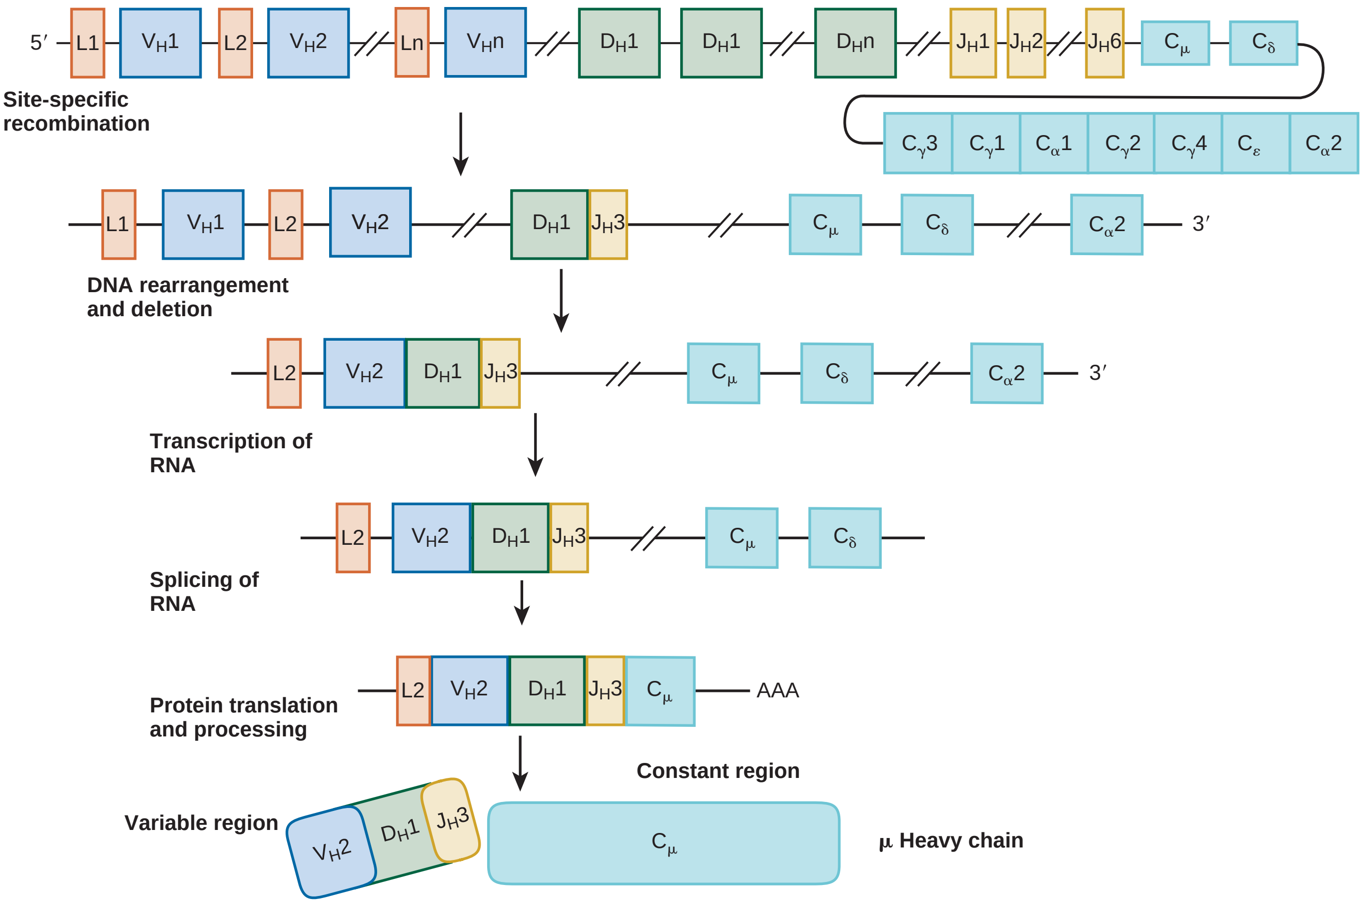

Figure 23-4 Immunoglobulin rearrangement. Immunoglobulin genes are encoded on human chromosome 14. Approximately 100 variable (V) genes, 50 diversity (D) genes, and 4 to 6 joining (J) genes make up the heavy-chain variable locus. The constant region consists of nine constant (C) genes. During immunoglobulin gene rearrangement, gene segments are deleted so that specific regions are joined to form one of many individual and characteristic genes.

light-chain loci. Pre-B cells lose CD34 expression, continue to express CD19 and CD10, and additionally upregulate CD20. The signaling cascade downstream of the pre–B-cell receptor is highly analogous to that of the mature BCR and activates a number of critical kinases, including Bruton tyrosine kinase (Btk) (discussed later). Boys born with mutations in Btk, manifested as X-linked agammaglobulinemia, have normal numbers of pro-B cells but lack pre-B cells and their progeny.[19] Thus formation of the pre–B-cell receptor along with activation of downstream signaling is a critical checkpoint in this stage of maturation.

Light-chain genes rearrange by a process similar to the recombination of heavy-chain genes. The variable region of the κ gene, located on chromosome 2, is spliced to the J gene segment to produce a VJ region, which then splices to the one constant region (C_κ). If nonproductive, the second κ locus will rearrange. If both attempts to rearrange the κ locus are unsuccessful, the λ locus, located on chromosome 22, will begin to rearrange. Productive rearrangement of any light-chain locus prevents further B-cell rearrangement and also generates survival signals. Pre-B cells that successfully rearrange a light-chain gene will then express mature IgM protein, which appears as surface IgM (sIgM) complexed to Ig-α and Ig-β, thus forming the BCR. Immature B cells are sIgM+, CD79+, CD19+, CD10+, and CD20+, but they have not acquired IgD expression, which occurs after peripheral maturation.

Expression of the tissue-specific recombination-activating genes RAG-1 and RAG-2 is required for recombination.[20,21] In addition, diversity is enhanced by the fact that the junctions between the D and J regions and the V and DJ regions are not precise; not only can the nucleotides vary, but one or more nucleotides (termed *N regions*), not encoded in the genome, may also be randomly inserted (N-region diversification). The nuclear enzyme terminal deoxyribonucleotidyl transferase (TdT) is the polymerase that adds random nucleotides to recombination junctions[22] and may have other roles.[23] Recruitment of TdT to the junctions appears to depend on the Ku molecule (specifically Ku80), a heterodimer that binds DNA ends and is required for V(D)J recombination and DNA double-stranded break repair.[24,25] Other proteins critical for nonhomologous end rejoining include Ku70, DNA-dependent protein kinase, DNA ligase IV, XRCC4, and the recently cloned protein Artemis.[26] Defects in the recombination machinery in genes such as RAG1, RAG2, DNA ligase IV, and Artemis all result in severe combined immunodeficiency (see Chapter 24).[27-29]

Peripheral B-Cell Maturation and Differentiation

Immature B cells must undergo further maturation in the spleen before acquiring the phenotype and functions of a naïve mature B cell. Naïve mature B cells are resting cells in G_0 phase; express the pan B-cell marker CD19, the marker CD20, and sIgM; and in contrast to immature bone marrow B cells, have lost CD10 expression and gained IgD expression. A similar population in the mouse is believed to be the common precursor for both follicular and marginal-zone B cells, named for their location within the spleen, discussed later.[30]

The development of early B precursors into immature B cells is a process that requires Ig rearrangement and expression of the pre–B-cell receptor and BCR, but it does not require recognition of antigen. Maturation to the naïve resting B cell involves selection of B cells that recognize antigen (positive selection) while eliminating B cells whose BCR recognize self-antigens with high affinity (negative selection). It has been proposed, on the basis of murine data, that determination of mature B-cell fate relies on the relative signal strength and specificity of the BCR, with higher and lower signal strength driving to the follicular and marginal-zone lineages, respectively.[30] Negative selection in particular is important for the deletion of potentially autoreactive clones and induction of B-cell tolerance. Indeed, it is estimated that 55% to 75% of immature B cells in humans recognize self-antigens,[31] and thus a minority of developing B cells pass the negative-selection test.

T-CELL ONTOGENY

T lymphocytes, like B lymphocytes and all other blood cells, are derived from self-renewing pluripotent HSCs. T cells are unique, however, in that their development also requires passage through a specific organ, the thymus. Indeed, the absolute requirement for the thymus is made clear by human congenital immunodeficiency states such as the DiGeorge syndrome, in which thymic organogenesis and therefore T-cell development are absent (see Chapter 24). Similar to B-cell ontogeny, the generation of millions of diverse T cells is accomplished by serial rearrangement of germline genes encoding the receptor for antigen recognition, the TCR. The bulk of peripheral T cells are of either the CD4+ helper or the CD8+ cytolytic lineages.

T-Cell Receptor Subtypes and Specificity

The TCR is a cell surface receptor capable of recognizing discrete antigens bound to the MHC or to MHC-related molecules expressed on the surface of APCs. TCRs are disulfide-linked heterodimers of either αβ or γδ proteins.[32-34] TCR αβ–bearing T cells constitute the vast majority of circulating T cells, most of which recognize peptide antigens bound to polymorphic MHC class I or class II molecules. A subset of TCR αβ T cells, representing approximately 1% of all T cells in humans, in contrast recognize lipid antigens bound to the MHC class I–related nonpolymorphic molecule CD1 and are termed CD1-restricted or NK T cells, discussed in a later section. TCR γδ–bearing T cells account for a tiny fraction of the circulating T cells in humans but are very prevalent in intestinal tissue and are thought to recognize nonpeptide antigens (discussed later). The functions of CD1-restricted TCR αβ T cells and TCR γδ T cells are somewhat distinct from those of conventional TCR αβ T cells. The discussion of intrathymic T-cell development in a subsequent section will focus on the major conventional subset of T cells.

Early T-Cell Commitment and Seeding

The molecular events associated with and responsible for commitment to the T lineage have been increasingly elucidated in both murine and human models over the last 10 years. The question of whether T-lineage commitment occurs within the thymus or the bone marrow has been actively investigated. In addition to pluripotent CD34+ HSCs, a number of other more committed progenitors in bone marrow with specific cell surface marker characteristics have been identified with T-lymphoid potential, primarily in the mouse, but these progenitors in general also retain the capacity to differentiate into other lymphoid lineages, including the B and NK lineages.[35] That various subsets identified in the human thymus similarly retain bilineage potential (i.e., NK/T potential or NK/dendritic cell potential) has led to the notion that the final steps in T-cell commitment occur in the thymus rather than the bone marrow.[36]

In addition to losing the capacity to differentiate into non–T-lineage cells in vitro, T-lineage commitment is characterized by the upregulation of certain cell surface markers (Fig. 23-5) and T-cell–specific genes important for the execution of downstream developmental programs.[37-39] CD34+ cells in human thymus can be further subdivided by the expression of CD38 and the MHC-like molecule CD1a, with progression from the CD34+ CD38– CD1a– stage to the CD34+ CD38+ CD1a– stage to the CD34+ CD38+ CD1a+ stage. Acquisition of CD1a+ is largely associated with the loss of NK, dendritic cell, and plasmacytoid dendritic cell differentiation in vitro.[36] Likewise, CD1a+ cells express the recombinase-activating gene products RAG1 and RAG2, and early TCR rearrangements are detectable after the acquisition of CD38 and CD1a. Transcription factors upregulated during these stages of early human T-cell commitment, whose requirement for T-cell development have also been demonstrated in gene-deficient mice, include GATA3 and Notch.[40-43]

Interactions between thymocytes and epithelial cells are critical for events in later thymic development, such as positive and negative selection, as detailed later, as well as for early commitment and development. The so-called *nude mouse*, which lacks expression of the epithelial transcription factor *Foxn1*, is born athymic, and humans lacking *FOXN1* have severe T-cell deficiency, alopecia, and nail dystrophy.[44,45] Unlike B cells, which can be induced in vitro to mature from precursors by co-culture on bone marrow stromal cells, T cells generally cannot be differentiated in vitro by this means, only when seeded into a three-dimensional source of primary thymic stroma, such as whole thymic organ culture. This distinction

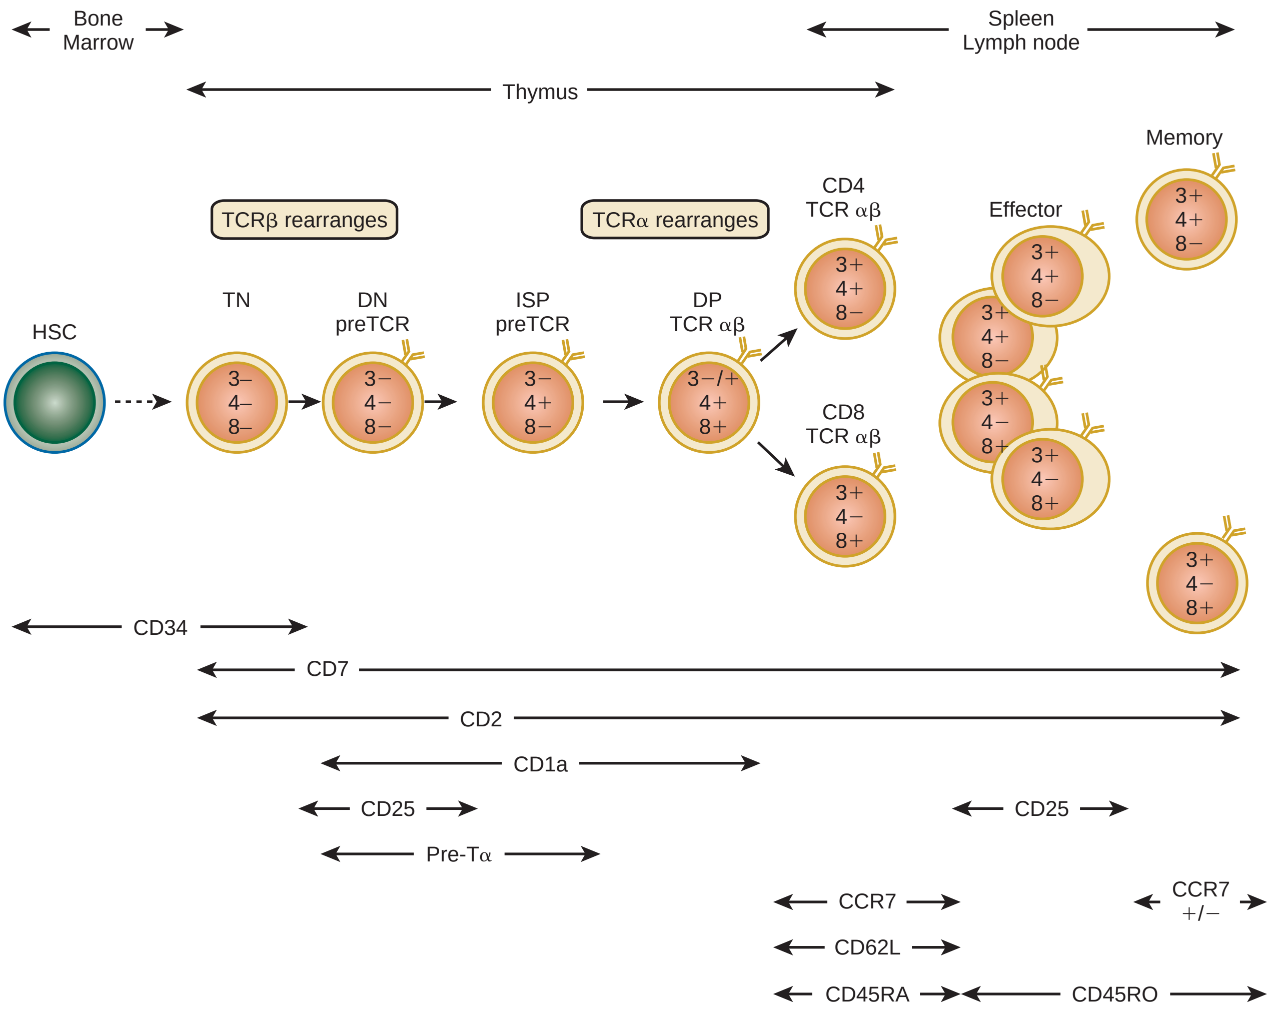

Figure 23-5 Overview of T-cell development. Pluripotent hematopoietic stem cells (HSC) in bone marrow commit to the T lineage, seed the thymus as early triple-negative CD3– CD4– CD8– (TN) thymocytes, and express the T-cell markers CD7 and CD2. T-cell receptor genes rearrange serially (TCRβ then TCRα), which leads to expression of the first pre–T-cell receptor (pre-TCR) and then the mature TCR αβ complex. (The CD3 components of the pre-TCR and TCR are omitted for simplicity.) Double-negative CD4– CD8– (DN) thymocytes upregulate both CD4 and CD8 after passing through an intermediate single-positive (ISP) stage to become double-positive CD4+ CD8+ (DP) thymocytes, which undergo positive and negative selection. During lineage commitment, either CD4 or CD8 is downregulated, thereby resulting in the formation of single-positive (SP) thymocytes with CD4+ thymocytes restricted to major histocompatibility (MHC) class II and CD8+ thymocytes restricted to MHC class I. Mature T cells in the spleen and lymph node that have not encountered cognate antigen express markers associated with the naïve state such as CD45RA and CD62L, and the pattern of surface markers changes with activation, acquisition of effector function, and further differentiation into memory T cells.

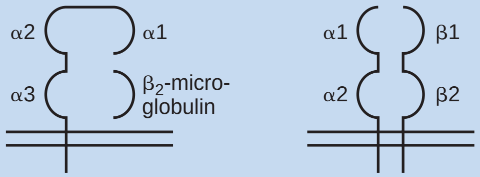
implies that specific soluble or cell-cell contact factors present only in the three-dimensional primary organ are required to engage developing thymocytes and induce their differentiation. The Notch signaling pathway, which is activated by the interaction of Notch ligands on epithelial cells and Notch family members on thymocytes, has emerged as one such factor.[46,47] Expression of activated Notch1 in human HSCs is sufficient to induce T-cell development in vitro and in immunodeficient mice,[48] and deletion of Notch1 from mouse thymocytes severely impairs early T-cell development.[49] Interestingly, primary three-dimensional thymic stroma expresses Notch ligands such as Delta-like 1 and 4, and this expression is lost when the architecture is disrupted.[50] Indeed, expression of Delta-like 1 or 4 in the OP9 bone marrow stromal cell line is capable of directing mouse and human uncommitted HSCs and even embryonic stem cells into the T lineage when co-cultured in a two-dimensional format in vitro.[46,51,52] This powerful system underscores the importance of thymocyte-epithelial interactions during intrathymic development and raises the intriguing possibility of differentiating and expanding T cells in vitro for use in human therapeutics,[53] which has been pursued in murine systems[54] and recently in expansion of umbilical cord blood units to expand access to this source of therapeutic stem cells.[55]

Stages of Intrathymic T-Cell Receptor αβ T-Cell Development and Spatial Considerations

T-lymphoid precursors that enter the thymus from the blood mature through a series of ordered developmental stages characterized by changes in cell surface markers,



Structure	MHC class I	MHC class II
	α chain + β_2-microglobulin	α + β chains
Molecular weight (Kd)	42 (α) + 12 (β_2m)	33 (α) + 29 (β)
Expression	All nucleated cells	Antigen-presenting cells, mono/macrophages, B cells, dentritic cells Thymic epithelial cells
Major loci	A, B, C	DR, DQ, DP
Minor loci	E, F, G, H	DM, DN, DO
	>100	>20
Peptide presented to	CD8+ T cells	CD4+ T cells
Peptide bound	8-9 amino acids	2-20 amino acids
Source of peptide	Endogenous antigens	Exogenous antigens

Figure 23-6 Characteristics of major histocompatibility (MHC) class I and class II molecules. MHC class I molecules are single transmembrane molecules noncovalently associated with β_2-microglobulin, whereas MHC class II molecules exist as heterodimers. CD8+ T cells recognize endogenous processed peptides (length 8 to 11 amino acids) embedded in the MHC class I groove, whereas CD4+ T cells recognize exogenous peptides (length 12 to 20 amino acids) embedded in the groove formed by MHC class II molecules. The major and minor loci are listed, as are important differences between the two classes.

sequential expression of the TCR genes, and predictable migration from the cortex to the medulla (see Fig. 23-5). The earliest thymocytes reside in the cortex, are CD34+, express pan-T-cell markers such as CD2 and CD7, but lack the TCR-associated αβ heterodimer and CD3-associated subunits of the TCR complex and the helper and cytotoxic mature T-cell coreceptors CD4 and CD8.[37] Hence, these thymocytes are CD3– CD4–CD8–, or triple negative. During αβ T-cell development, triple-negative thymocytes that succeed in rearranging a functional TCRβ chain express TCRβ complexed to the invariant pre-TCRα protein.[39] Pre-TCR signaling in thymocytes promotes rapid expansion and differentiation into double-positive (DP) thymocytes expressing both the CD4 and CD8 coreceptors and initiates rearrangement of the TCRα gene. In humans, in contrast to mice, there is an additional intermediate stage in which thymocytes express only CD4 and not CD8 (intermediate single positive [ISP]). DP thymocytes account for approximately 80% to 90% of the total thymocyte number and can be found in the cortex and at the corticomedullary junction. Although the majority of DP thymocytes die by apoptosis, those that successfully undergo positive and escape negative selection survive, commit to either the CD4/helper or CD8/cytotoxic lineage, and migrate to the thymic medulla before terminal maturation and export to the periphery.

T-Cell Recognition of Peptide-Major Histocompatibility Complex Complexes

A hallmark of the cellular immune response is antigen specificity, which is conferred by the rearranged and selected TCR on the surface of T lymphocytes. The TCR recognizes processed fragments of foreign proteins embedded in MHC molecules. There are two forms of MHC molecules: MHC class I (the major determinants are HLA-A, HLA-B, and HLA-C in humans) and MHC class II (the major determinants are HLA-DR, HLA-DQ, and HLA-DP in humans) (Fig. 23-6).[56] MHC class I molecules are composed of a 42-kd transmembrane, polymorphic α chain encoded in the MHC and noncovalently associated with a 12-kd soluble, nonpolymorphic (non-MHC) β chain termed β_2-microglobulin. X-ray crystallographic analysis of HLA molecules in which peptide was embedded[56] has demonstrated that the first two domains of the α chain both form α helices that together form a cleft (Fig. 23-7).[57] This cleft forms the binding domain for peptide antigen and accommodates a 9– to 11–amino acid fragment in an extended conformation; residues that interact with the MHC and those that interact with the TCR can be defined.[58,59] Polymorphism within the MHC itself serves to ensure variation in the affinity of peptide binding; the extraordinary MHC polymorphism within the species further ensures that any single microbe is unlikely to mutate such that it is unable to bind all MHC molecules in the population and therefore escape T-cell recognition.[60-63]

MHC class II molecules are formed by the noncovalent association of two transmembrane glycoproteins, αβ, both of which are polymorphic and encoded in the MHC.[56,60] Solution of the structure of MHC class II molecules has shown that a peptide-binding cleft is formed by the first domains of each of the αβ chains; however, the ends of the cleft are open, unlike the situation in MHC class I molecules (see Fig. 23-7).[56] The peptide-binding cleft of MHC class II accommodates processed peptides that are 10 to 30 (mean of 14) amino acids in length.[64,65] As with MHC class I, the genetic polymorphism of MHC class II determines the affinity and specificity of peptide binding and T-cell recognition.[64-66] Although MHC class I molecules are expressed constitutively on all human nucleated cells, MHC class II molecules are constitutively expressed only on B cells, monocyte-macrophages, and dendritic cells. Expression of MHC class II proteins may be induced on the surface

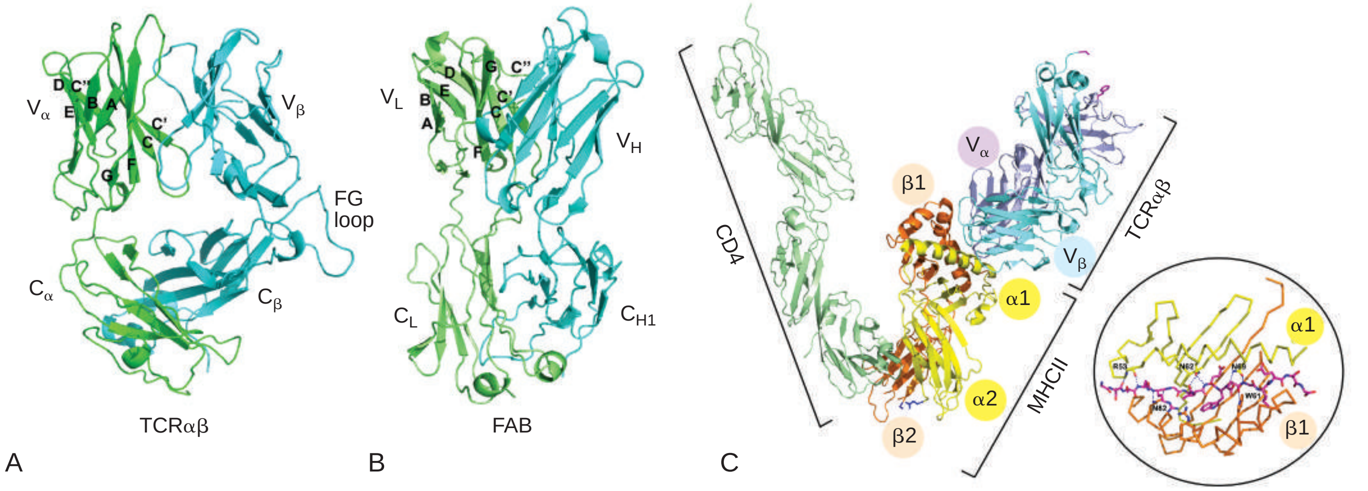


Figure 23-7 Comparison of the TCRαβ heterodimer with an immunoglobulin Fab and overall topology of the CD4/TCR/pMHCII ternary complex. **A** shows the N15 TCRαβ structure taken from the complex with the anti-Cβ FG loop Fab fragment of H57 antibody, the latter depicted in **B** as adapted from Wang et al.[268] The individual Ig-like domains are labeled, and the FG loop of Cβ indicated. The β strands of the Vα and VL domains are designated. Note that the TCRβ subunit and Fab heavy-chain fragment are shown in blue, and the TCRα subunit and Ig light chain are shown in green. **C** shows the overall orientation of the ternary complex (coordinates from PDB 3T0E). The representation shows the overall V-shaped CD4-MHCII architecture and how the MHC class II–restricted TCR must contact the MHCII molecule tangentially from the right in the figure. The TCRαβ will "bump up against the wall" of the α1 domain to provide a mechanical force facilitating mechanotransduction, as described in the text.[72] The *circular insert* shows a class II antigen-presenting platform with a peptide bound in the α1β1 groove. The peptide is in magenta and MHC sidechain to mainchain hydrogen bonds denoted. The view is from the TCR.

of monocyte-macrophages, fibroblasts, endothelial cells, and certain mesenchymal and epidermal cells by a variety of inflammatory mediators and cytokines such as IFN-γ. In humans but not in mice, MHC class II proteins can be inducibly expressed on T lymphocytes as well, thus rendering T cells capable of antigen presentation to other T cells. These two classes of MHC proteins generally interact with different classes of T lymphocytes: CD4+ T cells recognize peptide antigen in association with MHC class II molecules, whereas CD8+ T cells recognize peptide antigen in association with MHC class I molecules.[67,68] CD8 binds to invariant portions of the α3 domain of MHC class I and CD4 to a hydrophobic crevice between α2 and β2 domains[69-73] (see Fig. 23-7).

A growing number of drug allergies have been reported and shown to be a consequence of their drug binding to MHC molecules.[74-76] In general, peptides associate with HLA molecules by inserting parts of their amino acid residues into a set of six binding pockets in the HLA. The structure of these pockets is highly allele-specific, thereby dictating peptide-binding preferences for each HLA molecule. Remarkably, a recent study demonstrated that life-threatening drug-induced immune responses occur during abacavir treatment of HLA-B*57:01+ individuals as well as carbamazepine treatment of HLA-B*15:02+ patients through their binding to a specific pocket of the respective HLA molecules.[75] Drug binding shifts the repertoire of self-peptides normally complexed with that HLA molecule for surface display. As a consequence, self-peptides never before arrayed on the surface of cells within the patient's body are expressed and perceived by the T cell immune system as foreign. These led to the CTL-mediated destruction of such peptide arrayed target cells. It is likely that other drugs, environmental chemicals and toxins, and bacterial products function in a similar way, including interactions with class II MHC molecules. Given the immunologic basis of many cases of severe aplastic anemia (SAA), it is conceivable that the etiology of some or most SAA cases might be linked to such a mechanism.

T-Cell Receptor Rearrangement and Selection in the Thymus

Effective adaptive immunity relies on the random generation of a diverse repertoire of antigen-specific T cells, along with appropriate quality control measures to ensure that nonfunctional T cells are not needlessly allowed to mature fully. To achieve this goal, the TCR genes undergo somatic rearrangement in a serial fashion, and the growth and proliferation of developing T cells are tightly linked to signaling and transcriptional events downstream of functional TCR or TCR intermediates.

The four TCR gene clusters, α, β, γ, δ, are each composed of germline genes encoding discontinuous variable regions (Vα, Vβ, Vγ, Vδ), diversity regions (Dβ, Dδ), joining regions (Jα, Jβ, Jγ, Jδ), and constant regions (Cα, Cβ, Cγ, Cδ).[77] The TCRγ locus is situated on human chromosome 7, and the remaining three are located on human chromosome 14, with the TCRδ locus embedded between the V_α and J_α regions of the TCRα locus. The TCRβ germline genes consist of approximately 50 Vβ, 2 Dβ, 13 Jβ, and 2 Cβ genes, whereas the TCRα germline genes consists of at least 70 Vα, 60 Jα, and a single Cα gene. The TCRβ and TCRα loci have many more genes than the TCRδ or TCRγ loci do; however, the diversity of TCR γδ T cells is increased by the splicing of 2 D_δ regions to each other (VDDJ). Similar to the Ig genes in B cells, rearrangement of the TCR genes is carried out by

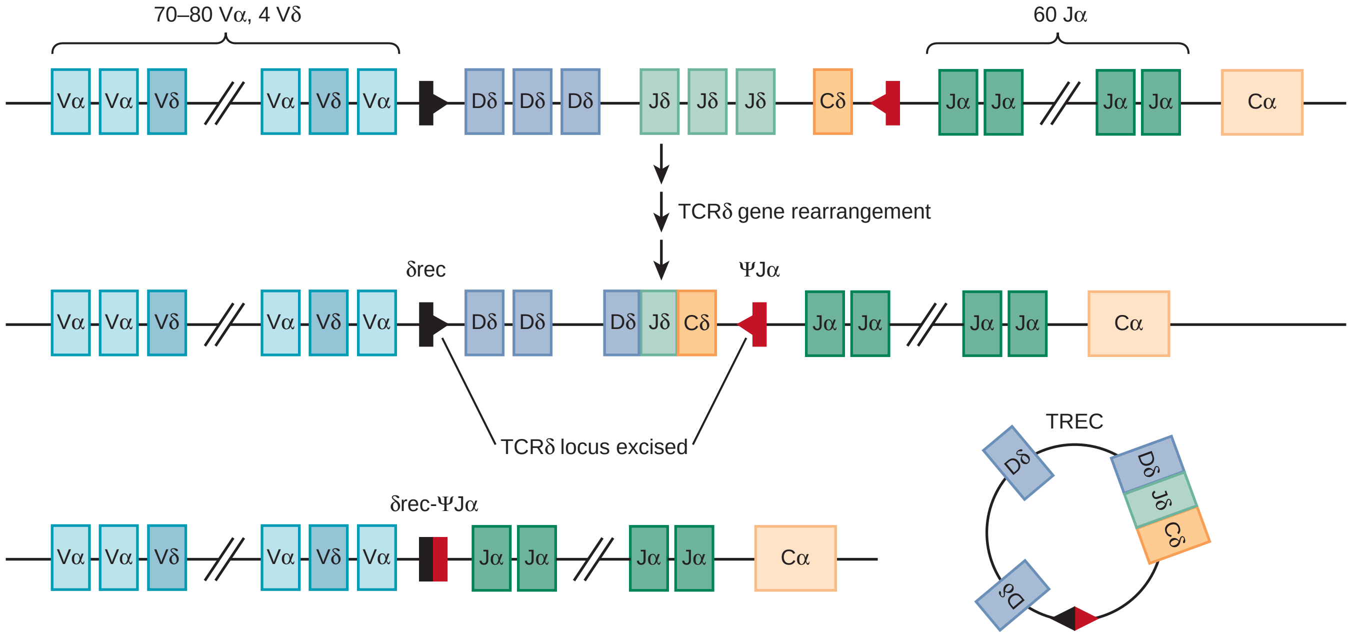

Figure 23-8 Formation of T-cell receptor excision circles (TRECs). The T-cell receptor α and δ (TCRα, TCRδ) loci are schematically depicted to show the basic rearrangement of variable (V), diversity (D), joining (J) and constant (C) regions. V_δ regions are interspersed between V_α regions, whereas the remainder of the TCRδ locus (D_δ, J_δ, C_δ) is embedded within the TCRα locus between the V_α and J_α regions. The *black box* and *red box* represent the δrec and ΨJα sequences, whereas the *black* and *red triangles* represent recombination signal sequences (RSSs) that recombination-activating gene (RAG) products recognize. The *first line* depicts the locus in the germline configuration. After TCRδ rearrangement, the D_δ, J_δ, and C_δ segments are randomly recombined. Thereafter, if the cell undergoes TCRβ and TCRα rearrangement, joining of δrec to ΨJα excises the TCRδ locus and results in an episomal circle of DNA containing the fusion of RSS signals. Polymerase chain reaction primers specific for this joining region can thus be used to detect the presence of the excision circle, an indicator of active rearrangement and T-cell neogenesis.

the RAG1 and RAG2 proteins, with serial somatic rearrangements between the V, D, J, and C regions. Although N-region diversification is found in both the TCRα and TCRβ genes, T cells do not undergo somatic mutation as B cells do and instead undergo limited further rearrangements after emerging from the thymus.[78]

Several major checkpoints regulate the development of TCR αβ and TCR γδ thymocytes.[79-82] First, serial rearrangement of the TCR gene clusters in an ordered fashion ensures that the TCRβ and TCRα genes are not rearranged in developing TCR γδ T cells. Thus in human thymocytes TCRγ and TCRδ loci rearrange first, during the triple-negative stage.[40] That human TCR γδ T cells generally have unrearranged TCRβ genes and that TCR αβ T cells generally have nonproductively rearranged TCRδ genes implies that only thymocytes that do not generate a functional γδ TCR go on to rearrange the TCRβ gene.[83] The molecular mechanisms controlling this process are still being elucidated. The second or so-called *beta selection checkpoint* occurs after TCRβ rearrangement. Cells that undergo productive rearrangement of the TCRβ locus express functional TCRβ protein that complexes to the invariant pre-TCRα protein and CD3 signaling complex, thereby resulting in the expression of pre-TCR. In gene-deficient mice, where beta selection is known to occur during a precise phase of the triple-negative stage of development, loss of a number of signaling molecules or transcription factors downstream of pre-TCR results in defective beta selection, failure of differentiation into DP stage, and lack of proliferation or apoptosis (or both).[84] Beta selection in humans begins during the CD34+ CD38+ CD1a+ stage and continues through the CD4 ISP and early DP stage of development (see Fig. 23-5).[40,83] Thus only thymocytes that express functional TCRβ are allowed to proliferate and proceed to TCRα locus rearrangement.

Before TCRα gene rearrangement, the TCRδ locus is excised by a nonproductive rearrangement between the δRec and ψJα regions[85] that generates an episomal circle of DNA or T-cell receptor excision circle (TREC), which is increasingly being used on both a research and a clinical basis to quantify thymic activity (Fig. 23-8).[86,87] The utility of TREC as a marker of new T cell generation has recently been used to detect severe combined immunodeficiency (SCID) in newborn dried blood spots,[88-90] and universal screening for SCID with TREC was endorsed for addition to the Recommended Universal Screening Panel in the United States by Secretary of Health and Human Services Kathleen Sebelius in May 2010.[91] Unlike the TCRβ locus, rearrangement of the TCRα locus occurs processively; that is, Vα-Jα recombination of 5’ J segments that are nonproductive or out of frame is followed by further rearrangement on the same allele to more 3’ J segments.[92] This process increases the chances of generating a complete TCR αβ protein from any single developing DP thymocyte. Successful rearrangement of the TCRα gene results in expression of the mature TCR αβ heterodimer and noncovalent association with CD3εγ, εδ, and ζζ dimer. This TCR complex appears during the late DP stage. These cells then undergo positive and negative selection (see the next section) and simultaneously commit to either the CD4 or the CD8 lineage to generate CD4 single-positive (SP) and CD8 SP thymocytes (see Fig. 23-5).

Positive Selection, Negative Selection, and CD4/CD8 Lineage Commitment

The massive proliferation of DP thymocytes results in TCR αβ thymocytes with an immense range of specificities, including many that are incapable of binding host MHC, cannot recognize host MHC complexed to endogenous peptide ligands, or have inappropriately high affinity for MHC–self-peptide and hence are autoreactive. Selecting only thymocytes with intermediate MHC–self-peptide affinity (so-called Goldilocks or just-right conditions) is critical for maintaining diversity of the repertoire while promoting self-tolerance.[93]

Positive selection is the term used to describe the process of selecting thymocytes capable of recognizing host MHC complexed to self-peptides generated from the processing of endogenous proteins. DP thymocytes are exquisitely prone to cell death in response to γ-irradiation, corticosteroids, exposure to anti-CD3 antibodies, or simply removal of the thymus from the body, and thus a positive signal via TCR-MHC/peptide interactions is required to rescue the small number of DP thymocytes destined to become SP thymocytes from cell death. Gene-deficient mouse experiments have demonstrated that multiple elements of TCR signaling are required for optimal positive selection, including TCR components (TCRα, CD3δ), early signaling molecules (GADs, ZAP70), late signaling proteins (RasGRP, calcineurin, ERK), and transcription factors (nuclear factor of activated T cells [NF-AT], Egr family members).[92,94-96] Interestingly, humans deficient in CD3δ and ZAP70 have been described who have discrepant development when compared with the knockout mouse counterparts. Deficiency of CD3δ in humans causes an earlier block in development at the CD4− CD8− stage, well before the development of DP thymocytes.[97,98] ZAP70 deficiency results in selective deficiency of CD8 SP thymocytes and mature CD8+ T cells.[99-101] Likewise, although in the mouse interaction of DP thymocytes with MHC on radioresistant cortical thymic epithelium is probably the dominant requirement for positive selection, the source of MHC and the relative contributions of MHC from thymic epithelium, thymic dendritic cells, or other thymic APCs to positive selection in humans are less clear.

Negative selection is the term used to describe the process of removing thymocytes that are self-reactive, also termed *central tolerance,* by clonal deletion.[102,103] This is the first and major mechanism for control of autoimmunity, although clones that escape deletion in the thymus are subject to peripheral tolerizing influences (discussed later). In mice negative selection can be mediated by cortical epithelium, medullary epithelium, and medullary dendritic cells. However, it was never clear how thymocytes reactive against self-antigens expressed only in peripheral tissues, such as islet cells, were selected against in the thymus. In other words, how are these tissue-specific proteins expressed in the thymus? More recently, murine and human studies have revealed that all three cell types, medullary thymic epithelial cells (mTECs) in particular, exhibit promiscuous gene expression and transcribe a broad range of tissue-specific, nonthymic antigens.[104] This insight helps explain how developing thymocytes reactive against nonthymic proteins can be centrally deleted during negative selection. A newly discovered gene, *AIRE* (autoimmune regulator), is a factor shown to control the transcription of tissue-specific antigen expression in murine mTECs.[105] Simultaneously, this gene was shown to be responsible for the autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome, characterized by chronic mucocutaneous candidiasis, hypoparathyroidism, adrenal insufficiency, and other organ-specific autoimmune manifestations.[106,107] Thus this disease may be the first example of failure of negative selection underpinning a human monogenic autoimmune disorder.

Maturation of CD4 and CD8 SP thymocytes from DP thymocytes occurs concurrently with positive selection and results in "matching" of coreceptor to MHC restriction with downregulation of the opposite coreceptor. The mechanisms controlling the CD4/CD8 lineage decision are separable from those governing positive selection[108] and have been the subject of active investigation in murine models.[109-112] Patients with defects in a number of genes that control MHC class II expression, including *RFXANK, RFX5, RFXAP,* and *CIITA,* all manifest the so-called *bare lymphocyte syndrome*, a rare autosomal recessive disorder characterized by decreased numbers of CD4+ T cells, deficient helper function, and absence of specific antibody production because of lack of CD4-mediated B-cell maturation.[113]

THE SPLEEN

Historical Perspective

A complete understanding of the adaptive immune system requires a discussion of the structure and function of the spleen, a critical secondary lymphoid organ with both immunologic and nonimmunologic functions. Since ancient times the spleen has occupied a mysterious niche among organs within the human body. Its proposed functions and necessity for good health were subjects of debate and discussion for centuries.[114] Hippocrates believed that the spleen helped balance the body's "humors," a process necessary to promote harmony and stability. Plato and Aristotle further suggested, on the basis of its location, that it assisted or balanced the liver. Galen noted the anatomic connections among the spleen, liver, and stomach and concluded that the spleen had true digestive functions that included the filtering of humoral impurities. Subsequently, the spleen gained a reputation for controlling feelings and emotions, including laughter, ill temper, melancholy, and others. Shakespeare often referred to the spleen as an organ of anger, merriment, or other strong emotion. During the Renaissance, when the study of anatomy and physiology became popular, the spleen's microscopic patterns supported a role for filtration; however, only circulatory connections between the spleen and the stomach, liver, and other digestive organs could be identified. Moreover, survival of both animals and humans after surgical splenectomy demonstrated that the spleen was not absolutely required for life. Only in the modern era, with the discovery of individual blood cells, have investigators begun to elucidate the true functions of the spleen. We now recognize that the spleen has vital roles in blood filtration and immunologic competence.

Anatomy and Physiology

The spleen can be identified in human embryogenesis during week 5 of gestation, although the development of characteristic splenic architecture with influx of red and white blood cells occurs much later in gestation. At birth the spleen weighs about 10 g, then 30 g at 1 year of age, 60 g by 5 years, and approximately 200 g in adults.[115] Located in the left anterior aspect of the rib cage, the spleen can have a triangular, crescent, or rhomboidal shape. Spleen size is usually estimated clinically by how far below the left costal margin the tip of the spleen can be palpated. Frequently, an enlarged spleen is most easily palpated at the midclavicular line, but it can extend prominently toward the midline or even to the midaxillary line in some patients.

The spleen receives 3% to 5% of the total cardiac output, thus making it a highly perfused organ.[116] Blood enters and leaves the spleen primarily through the splenic artery and vein, respectively, both located at the hilum on the concave (medial) side of the organ. Within the splenic parenchyma, the splenic arterial branches have little overlap, thereby allowing classification of the spleen into lobes and segments separated by relatively avascular planes.

Histologically, the spleen can be separated into two distinct regions, the red pulp and the white pulp, so named because of the blood cells most commonly found in each area. These two regions provide the vital functions of blood filtration and immunologic response, respectively, which are made possible through a unique circulation pattern found within the spleen. Figure 23-9 illustrates the arterial and venous circulations of the spleen and the close proximity of the red and white pulp.

The white pulp consists primarily of collections of lymphocytes and macrophages that form small white nodules (1 to 2 mm in diameter) distributed throughout the splenic parenchyma. As the largest arteries within the spleen branch progressively into the smallest arterioles, the white pulp can be recognized as a circumferential ring of leukocytes that surround the vessel, also known as the *periarterial* (or periarteriolar) *lymphoid sheath* (PALS). Whereas blood cells tend to continue within the vessel, plasma elements enter the PALS by way of tiny vessels that arise perpendicular to the flow of blood. Soluble antigens are thus herded into the white pulp, where they encounter dendritic cells and macrophages that function as professional APCs and allow proper immune stimulation of T and B lymphocytes.

The PALS consists primarily of T lymphocytes, and this cylindrical cuff of cells becomes thinner as the artery becomes smaller. Spheroidal lymphoid follicles arise at intervals from the PALS, usually where arterial branch points occur, and these follicles contain primarily B lymphocytes (Fig. 23-10). The primary follicles contain naïve mature B cells that co-express IgM and IgD; secondary follicles contain activated B cells within its germinal center (GC), all termed *follicular B cells*. Naïve follicular B cells in the primary follicle are CD27–, in contrast to memory B cells, discussed later, which express CD27.[117,118] In the mouse T cells congregate around the central arteriole in the so-called PALS studded by follicles and GCs containing B cells; the marginal zone delineates

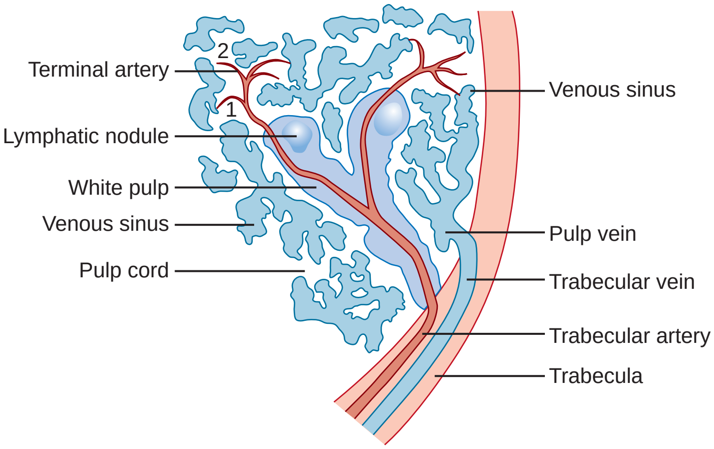

Figure 23-9 Blood circulation in the spleen. As blood enters the spleen, the arterial vessels are surrounded by lymphatic sheaths and nodules that constitute the white pulp. The majority of arterial blood terminates in the venous sinuses (red pulp), where filtration and quality control of erythrocytes take place. Erythrocytes return to the venous circulation via the venous sinuses. *(From Fawcett D:* A textbook of histology, *ed 11, Philadelphia, 1985, Saunders, p. 474.)*

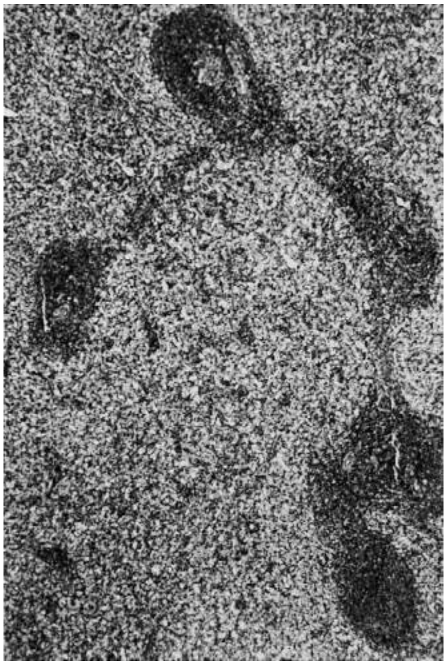

Figure 23-10 Lymphoid follicles in the white pulp appearing as budlike outgrowths from the periarteriolar lymphoid sheath. *(From Neiman RS, Orazi A, editors:* Disorders of the spleen, *ed 2, Philadelphia, 1999, Saunders, p. 10.)*

the white pulp from the red and surrounds both the follicles and PALS. In humans, by contrast, T cells and B cells tend to interdigitate, and the follicles are encompassed within the PALS. The marginal zone in humans is positioned around the follicles, does not envelop the PALS, and is not in direct contact with red pulp.[119] Marginal-zone B cells are IgM+ IgD– CD1c+ CD23– and thus are distinguished from follicular B cells (IgM– IgD+ CD1c– CD23+).[30] Additionally, marginal-zone B cells express high levels of CD21 and as a result are highly responsive to complement. Finally, in contrast to rodent marginal-zone B cells, which are sessile, marginal-zone-like B cells in humans can circulate in blood and have a memory phenotype, being IgM+ IgD+ CD27+.[120]

The red pulp represents a large open circulation within the spleen through which erythrocytes pass slowly for filtration and culling functions. The red pulp contains the sinusoids, which are lined by macrophages, and the splenic cords, which lie between the sinusoids and are composed of connective tissue, epithelial cells, monocytes, and macrophages. After plasma is redirected toward the white pulp, the blood cells that continue through the splenic circulation are mostly erythrocytes, and they form the red pulp as they exit the arteries. Occasionally, erythrocytes pass directly from the arterial to the venous circulation by way of traditional endothelialized capillaries, a process known as the *closed (rapid) splenic circulation*, which is primarily nutritive. Much more commonly, however, erythrocytes leave the arterial circulation and empty into large pools called the *splenic cords*, where they encounter macrophages and other immune effector cells. Erythrocytes must survive these intimate encounters in this hypoxic and acidic environment and then pass from the cords through an endothelialized barrier into the splenic sinuses and finally back to the venous circulation. This open (slow) circulation allows careful filtration of individual erythrocytes, with repair or phagocytosis of cells that cannot successfully negotiate the return trip.

Important Functions

The spleen provides several important immunologic functions. Skimming of plasma into the PALS allows particulate antigens to interact with dendritic cells and other APCs, which initiates the immune response for T- and B-lymphocyte response and proliferation. Polysaccharide antigens in particular require this unique immunologic environment for optimal antibody response.[121,122] Intravenous antigens, such as those found during infection or after immunization, are primarily processed by the spleen.[123] Not surprisingly, normal splenic function is required for optimal early (IgM) response to most intravenous antigens, as well as the secondary (IgG) response.[124] In contrast, antigens administered by the intramuscular or subcutaneous routes do not require normal splenic function for a robust immune response.[125,126] Finally, bloodborne bacteria, particularly encapsulated organisms, are removed by splenic macrophages located in the PALS and in the cords. Without a functioning spleen, patients are susceptible to overwhelming bacterial sepsis and exaggerated parasitemia from *Plasmodium, Babesia,* or other organisms.[127,128] The interaction between specialized T helper cells and follicular B cells in the GC is further described in later sections.

The spleen also has nonimmunologic functions. All RBCs pass through the spleen many times each day.[129,130] The spleen serves as an efficient filter for erythrocytes and is able to perform grooming (removal of antibodies or other surface molecules), culling (destruction of cells), and pitting functions (removal of intracellular material). While moving slowly through the hostile environment of the splenic cords, erythrocytes are carefully examined for abnormalities, a process constituting a biologic form of quality control. Macrophages in the red pulp identify abnormal erythrocytes, such as those that have IgG or complement on their surface, and either remove a portion of their membrane or fully engulf them. Newly made reticulocytes spend their first day or two in the spleen,[131] during which the cells appear to be groomed with removal of cytoplasmic organelles and surface adhesion molecules. Normal mature erythrocytes, in contrast, typically endure macrophage scrutiny without difficulty. To leave the red pulp, erythrocytes must then pass back from the splenic cords through potential spaces in the endothelial lining of the splenic sinuses. To negotiate these tiny apertures, known as the *cords of Billroth*, the erythrocytes must deform themselves substantially (Fig. 23-11). Cordal macrophages phagocytose erythrocytes that cannot deform themselves sufficiently, such as senescent cells; as erythrocytes age, they lose volume, gain density, and eventually lose the deformability that allows reentry into the splenic sinus. In certain pathologic conditions, such as immune-mediated hemolytic anemia, as well as a variety of erythrocyte membrane, hemoglobin, and enzyme disorders, younger erythrocytes will also be trapped in the splenic cords. Erythrocytes with intracellular inclusions, such as nuclear remnants known as *micronuclei* (Howell-Jolly bodies), denatured hemoglobin (Heinz bodies), siderotic granules (Pappenheimer

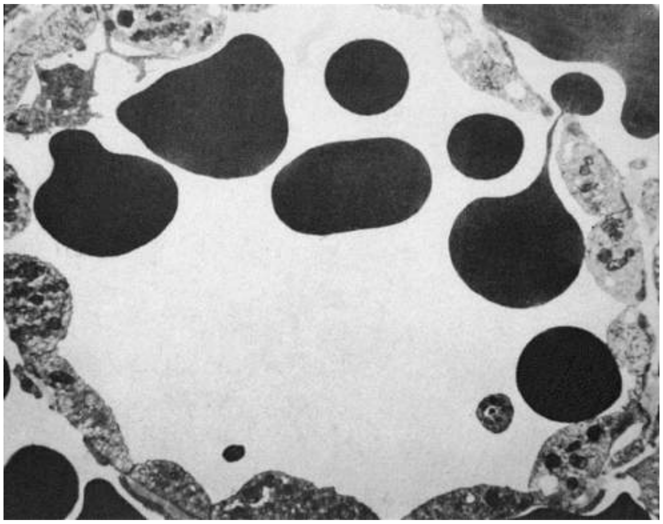

Figure 23-11 Deformation of erythrocytes returning from the splenic cords (red pulp) back into the venous sinus. The erythrocytes must pass through very small potential spaces in the sinus wall known as the *cords of Billroth*. *(From Neiman RS, Orazi A, editors:* Disorders of the spleen, *ed 2, Philadelphia, 1999, Saunders, p. 18.)*

bodies), and malarial parasites, have their inclusions "pitted" out before they pass through the endothelial slits and return to the circulation.

To a much lesser extent, the human spleen can also serve as a reservoir for circulating blood cells. Approximately 50 mL of blood is usually contained in a normal spleen, as well as 30% of the platelet mass. In the abnormal state (discussed later), the spleen can enlarge and trap a larger portion of the circulating blood cells, a condition known as *hypersplenism*. The spleen may also serve a small role in iron metabolism and homeostasis. Unlike the spleen in other species, however, it has no appreciable role in human hematopoiesis.

Abnormalities of the Spleen

Congenital Asplenia and Polysplenia

Congenital asplenia is found in children with the rare Ivemark syndrome, in which the body has bilateral "right-sidedness" with trilobed lungs and a centralized liver.[132] Cardiac defects are common, as well as a risk of infection.[133] In even rarer cases patients have congenital asplenia with no other abnormalities.[134,135] This resembles mice with a targeted deletion of Hox11 (also called *Tlx1*).[136] No defects in Hox11 have been discovered in humans with isolated congenital asplenia. Instead, about half of the patients have a heterozygous inactivating mutations in RPSA (ribsomal protein SA), a component of the small subunit of the ribosome.[137] How haploinsufficiency of a part of the ribosome, which is needed in all cells, specifically blocks development of the spleen remains a mystery. A heterozygous missense mutation in Nkx2-5 has also been found in one kindred.[138] This makes sense because Nkx2-5 interacts with Pbx1 and p15Ink4b to regulate spleen organogenesis in mice.[139]

A number of genes in humans and mice are linked to asplenia combined with multiple defects in other tissues. Examples include: Nkx2-3,[139] Nkx3-2 (or Bapx1),[140,141] Sox11,[142] Wt1,[143] Pbx1,[144] Tcf21 (or Pod1),[144] and HuR.[145] Interestingly, HuR interacts with a putative regulatory element in the Hox11 gene.[146]

Uptake of radionuclide by functioning splenic tissue can be difficult to document because the anatomic features are distorted and liver tissue can obscure any splenic uptake. Circulating erythrocytes with Howell-Jolly bodies or intracellular vesicles that appear as pits or pocks allow the diagnosis of asplenia to be established noninvasively.[147] Figure 23-12 illustrates the Howell-Jolly bodies that are found in the peripheral blood smear of an asplenic person. The converse arrangement of bilateral "left-sidedness" leads to congenital polysplenia with several spleens of varying size. In most patients the splenic tissue in polysplenia has normal function. Cardiac defects are common, as well as hepatobiliary abnormalities.[148,149]

Accessory spleens can be identified in 15% of normal persons.[150] In most of these individuals, a single accessory spleen measuring only 1 to 2 cm in diameter is present either in the splenic hilum or in the tail of the pancreas. Multiple accessory spleens can exist, however, as well as ectopic spleens in locations ranging from the abdomen to the pelvis and scrotum. The function of accessory spleens depends on the quality and quantity of blood flow; in most instances their filtration capabilities are minimal, but antibody responses may be present.

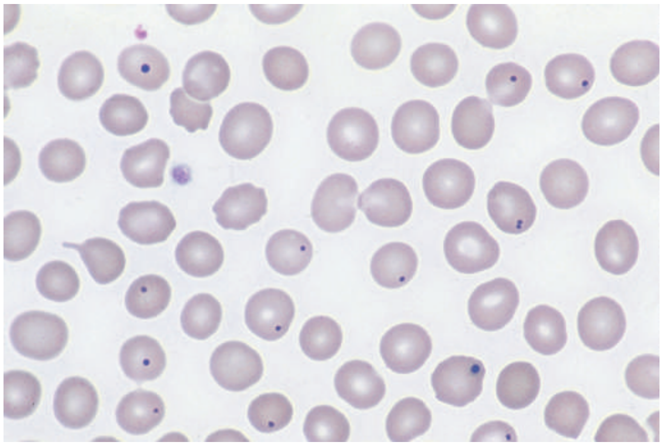

Figure 23-12 Howell-Jolly bodies in peripheral blood erythrocytes. These nuclear remnants are identified as small inclusions within circulating erythrocytes and have several characteristic and required features by light microscopy: (1) they are spherical inclusions 0.5 to 2.0 μm in diameter, about the size of a small platelet; (2) they have a smooth contour and no surrounding halo, which distinguishes them from platelets juxtaposed to an erythrocyte; (3) they are always in the same focal plane as the erythrocyte because they are intracellular; (4) they are never refractile, unlike talc or dust particles; and (5) they are homogeneous in appearance, unlike other intracellular inclusions such as Pappenheimer bodies or malarial parasites. Howell-Jolly bodies are normally removed when erythrocytes pass through the cords of Billroth into the venous sinus. Their presence in peripheral blood indicates lack of splenic filtrative function.

Splenosis and Splenoptosis

Splenoptosis, or wandering spleen, occurs when the spleen is not fixed within the retroperitoneum.[151] The resulting mass can be palpated anywhere in the abdomen and may require reattachment (splenopexy) or even splenectomy if symptoms of sequestration or torsion develop.[152] *Splenosis* refers to the autotransplantation of splenic tissue into the omentum or peritoneal surfaces of the abdominal cavity. Splenosis typically occurs after fracture or rupture of the spleen as a result of spillage and subsequent implantation of splenocytes. Although some protection against infection may be afforded by splenosis,[153] filtering functions and immunologic responses are limited by the relatively small total amount of splenic tissue and reduced blood supply.

Splenic Sequestration

Sequestration refers to enlargement of the spleen that occurs when blood enters the organ but is unable to exit properly. This condition is most often observed in children with sickle cell anemia when venous return of blood is hindered by intrasplenic sickling of erythrocytes within the red pulp. Splenic sequestration also occurs in other settings with abnormal erythrocytes, however, including congenital spherocytosis. Splenic sequestration can develop acutely with sudden pooling of blood within the spleen and result in rapid and painful expansion of the splenic parenchyma and capsule. Children exhibit pallor, fatigue, severe anemia, and occasionally hypovolemic shock.[154] Occasionally, splenic sequestration develops over a period of days or weeks and is then termed *subacute* or *chronic* because it is accompanied by relatively asymptomatic splenomegaly.

Hypersplenism

Hypersplenism refers to the condition of splenomegaly with non–immune-mediated trapping of peripheral blood cells and results in mild to moderate cytopenia.[155] Hypersplenism can develop in patients with abnormal erythrocytes, metabolic storage disorders, or other causes of chronic congestive splenomegaly. In these clinical settings, the spleen first enlarges because of progressive trapping of erythrocytes or storage material and then subsequently becomes a reservoir for all circulating blood cells. Typically, the peripheral platelet count is lower than normal, but the leukocyte count can also be low. If surgery is required, peripheral blood counts normalize after splenectomy.

Surgery Involving the Spleen

Although the spleen has important hematologic and immunologic functions, in some instances surgical removal is beneficial. A variety of congenital anomalies of the spleen, as well as numerous pathophysiologic processes, are indications for splenectomy.

Benign tumors of the spleen are relatively rare in childhood but primarily include congenital cysts (epidermoid or lymphangiomatous) or pseudocysts that result from liquefaction of splenic parenchyma after infarction or hemorrhage. These tumors may require splenectomy, depending on their size. Malignant splenic tumors are almost always lymphomatous or leukemic in origin, with cancerous cells found diffusely or in a nodular pattern throughout the splenic parenchyma. Perhaps somewhat surprisingly, very few solid tumors metastasize to the spleen. As a general guideline, splenectomy is not usually indicated in the setting of malignancy.

Splenomegaly requiring splenectomy can develop in a variety of clinical settings, including metabolic storage disorders such as Gaucher disease, transfusion-acquired iron overload from chronic erythrocyte transfusions, and splenic congestion resulting from portal hypertension. Commonly, splenectomy is the recommended therapeutic option for splenic enlargement in patients with primary erythrocyte abnormalities. Congenital hemoglobin, enzyme, and membrane disorders lead to trapping of the abnormal erythrocytes within the splenic cords and gradual expansion of the red pulp. In these settings splenectomy can relieve the signs and symptoms of splenomegaly, including abdominal discomfort, anemia, hypersplenism, and dependence on transfusions.

Total surgical splenectomy is generally performed by open laparotomy by way of a left subcostal incision. Laparoscopic splenectomy has become a popular and safe alternative in children[156,157] but requires careful attention and may be technically difficult with very large spleens. With the laparoscopic approach, small amounts of residual splenic tissue may be left or accessory spleens may be missed,[158] which can be a problem for patients with immune-mediated hematologic disorders. When splenectomy is recommended for autoimmune hemolytic anemia (AIHA) or immune thrombocytopenic purpura (ITP), all splenic tissue must be removed to prevent recurrent autoantibody production. Over the past decade subtotal (partial) splenectomy has become a viable therapeutic alternative to total splenectomy. The partial splenectomy approach is possible because the spleen can be divided into distinct lobes and segments.[159] Removal of 80% to 90% of the enlarged spleen usually provides relief from splenomegaly while retaining sufficient splenic tissue for immune competence. Partial splenectomy has been used successfully in children with nonparasitic splenic cysts,[160] hereditary spherocytosis,[161] homozygous β-thalassemia[162] and sickle cell disease,[163] although splenic regrowth may limit its long-term efficacy.[164] Even children with massive splenomegaly can successfully undergo partial splenectomy.[165] Animal studies suggest that a third of the normal spleen mass is required for normal plasma filtration and antibody formation.[166] Compared with splenic tissue reimplanted either by surgical autotransplantation or splenosis,[167,168] partial splenectomy provides superior retained immune function. Laparoscopic partial splenectomy combines these two new approaches and may represent an ideal option for selected patients who require surgical splenectomy; it is becoming more commonly available for children.[169,170]

The primary danger after total splenectomy is fatal bacterial sepsis, sometimes referred to as *overwhelming postsplenectomy infection (OPSI)*. First recognized more than 50 years ago,[171] bacteremia evolving rapidly into fatal sepsis with or without meningitis can abruptly develop in a patient without splenic function. Pathogens associated with OPSI are primarily encapsulated bacterial organisms and include *Streptococcus pneumoniae, Haemophilus influenzae* type b, and *Neisseria meningitidis*. The presumed pathophysiologic origin of OPSI is loss of plasma filtration by the spleen, which allows bacteria to multiply within the bloodstream and evolve from low-grade bacteremia to fulminant sepsis. Risk factors for OPSI include younger age at initial clinical evaluation, younger age at splenectomy, and failure to comply with prophylactic antibiotics or vaccinations. The true risk for the development of OPSI has been estimated in two large studies, although many of the patients were from the prevaccination era. First, in a literature review covering 35 years from 1952 to 1987 (5902 patients), the incidence of infection after splenectomy in children younger than 16 years was 4.4% with a mortality rate of 2.2%; for adults the corresponding values were 0.9% and 0.8%, respectively. Children younger than 5 years and especially infants had a much higher risk for sepsis.[172] In a later survey of 226 splenectomized patients with hereditary spherocytosis that included 5461 years of postoperative follow-up, the estimated mortality rate was 0.73/1000 years for the entire group, but somewhat higher for children.[173] The introduction of polysaccharide and now protein-conjugated vaccines has greatly helped decrease the incidence of pneumococcal bacteremia and sepsis and will help offset the lack of splenic filtration function for children undergoing splenectomy. However, even with the use of presplenectomy immunization, prophylactic antibiotics, and prompt medical attention for fever, a splenectomized child still has a finite risk of OPSI developing with substantial morbidity and mortality.

B-CELL ACTIVATION AND FUNCTION

An appropriately diverse population of naïve B cells should collectively be capable of responding to any soluble antigen that the individual encounters, yet there are very few naïve B cells that are capable of recognizing any given antigen. B-cell activation that occurs in the appropriate costimulatory context is the trigger for clonal expansion of the responding B cell. A portion of these activated B cells differentiate into memory cells, which rapidly respond on reencounter with the same antigen, and another portion into plasma cells, which continuously secrete antibodies (see Fig. 23-2). In addition, activated B cells undergo isotype switching from low-affinity IgM to high-affinity IgG, IgA, or IgE and somatic hypermutation, also called *affinity maturation*, thus further ensuring that the humoral response is exquisitely specific, effective, and long lasting. Recognition of antigen by the BCR occurs with or without T-cell help, depending on the type of antigen, so-called *thymus-dependent* (TD) or thymus-independent (TI) antigens. BCR signals that occur during TD responses are modulated and enhanced by cell-cell contact with T cells by way of critical costimulatory molecules, discussed further in the section on T-cell costimulation.

Thymus-Dependent Versus Thymus-Independent B-Cell Responses

Unlike T cells, which recognize either short peptides or small lipid molecules that must be presented in the cleft of an MHC or MHC-like molecule, the BCR is capable of binding a variety of antigens, including soluble proteins and polysaccharides. Recognition of protein antigen generally requires cooperation with T cells, or T-cell help, and thus such antigens are TD antigens. Naïve follicular B cells in lymph node follicles or the spleen recognize their cognate antigen while contacting a helper T cell specific for the same antigen; linked T-B interaction then fuels the formation of a key structure, the GC, where isotype switching, somatic hypermutation, memory cell generation, and plasma cell differentiation occur.

TI antigens are classified as type 1 or type 2 (TI-1 and TI-2).[174] TI-1 antigens are bacterial components that can trigger B-cell activation regardless of Ig specificity and thus lead to polyclonal activation. These components fall into the general category of pathogen-associated molecular pattern (PAMP) molecules, the canonic example being lipopolysaccharide (LPS). PAMP molecules activate B cells by binding to a distinct family of receptors, the Toll-like receptors (TLRs), thereby accounting for their independence from Ig. The Ig secreted in response to TI-1 antigens is typically low-affinity IgM because TI-1 antigen binding does not induce class switching.[175]

TI-2 antigens, in contrast, are molecules that have a repetitive structure and activate B cells by cross-linking of multiple BCRs on a single cell, hence leading to specific clonal antibody production. These antigens are typically bacterially derived polysaccharides, such as those found in the coating of encapsulated organisms. Marginal-zone B cells are important for responses to TI-2 antigens, and the fact that marginal-zone B cells typically take years to mature in children probably underlies the lack of response of children younger than 2 years to polysaccharides.[30] The spleen is the major site of TI-2 antigen recognition, and the antibody produced again is often IgM, although IgG responses also clearly occur. Class switching in this instance does not depend on cognate T-cell help but probably is enhanced by noncontact T-cell factors such as the cytokine interleukin-4 (IL-4).[174]

B-Cell Receptor Triggering and Signaling

B-cell activation involves a complex array of molecular signaling events. The signaling cascades that emanate from the BCR are highly analogous to those triggered in T cells by the TCR and involve a host of kinases, adaptor proteins, and other enzymes.

In brief, B-cell activation commences with engagement of surface Ig, which initiates receptor oligomerization, an event that depends on B-cell coreceptors such as the stimulatory CD19 and CD21 receptors and the inhibitory low-affinity FcR.[176,177,178,179] In addition, aggregation of Ig receptors takes place in specialized membrane microdomains, termed *lipid rafts,* that are characterized by their cholesterol- and sphingolipid-rich content.[180-183] In cellular systems lipid rafts have been postulated to function in intracellular trafficking, apical sorting, and signal transduction.[184,185] In both T and B lymphocytes, lipid raft components may function as a potential signaling platform to foster the aggregation and co-localization of signaling proteins.[180,186-188]

Within the lipid raft, the Ig molecule transmits signals through the associated Ig-α and Ig-β molecules (Fig. 23-13), together termed the *BCR;* the BCR, like other members of the immune recognition receptors, has no intrinsic tyrosine kinase activity. On oligomerization the cytoplasmic domains of Ig-α and Ig-β become tyrosine phosphorylated on so-called immunoreceptor tyrosine–based activation motifs (ITAMs) with the amino acid consensus sequence D/ExxYxxL/Ix7YxxL/I. Phosphorylation of ITAMs is mediated by Src kinase family members, notably Fyn, Blk, and Lyn (see Fig. 23-13),[187,189,190] which then recruit the critical tyrosine kinase Syk by way of its Src homology 2 (SH2) domains. Syk itself, when bound, requires activation either by autophosphorylation or phosphorylation by Src kinases, and thus clustering of multiple ITAM-bearing BCRs, Src kinases, and Syk is required to achieve a threshold of activation that initiates downstream cascades.[191]

Activation of Syk, similar to activation of ZAP70 in T cells (see later), is a crucial linchpin in BCR signaling. Syk itself functions as a tyrosine kinase and is capable of phosphorylating key substrates, which then activate three main signals, the protein kinase C (PKC), intracellular calcium, and Ras pathways. Activation of these pathways occurs by assembly of a macromolecular complex of critical signaling molecules clustered on an adaptor protein known as the *B-cell linker protein* (BLNK) or SLP65.[190] Recruitment of a member of the Tec kinase family, Btk,

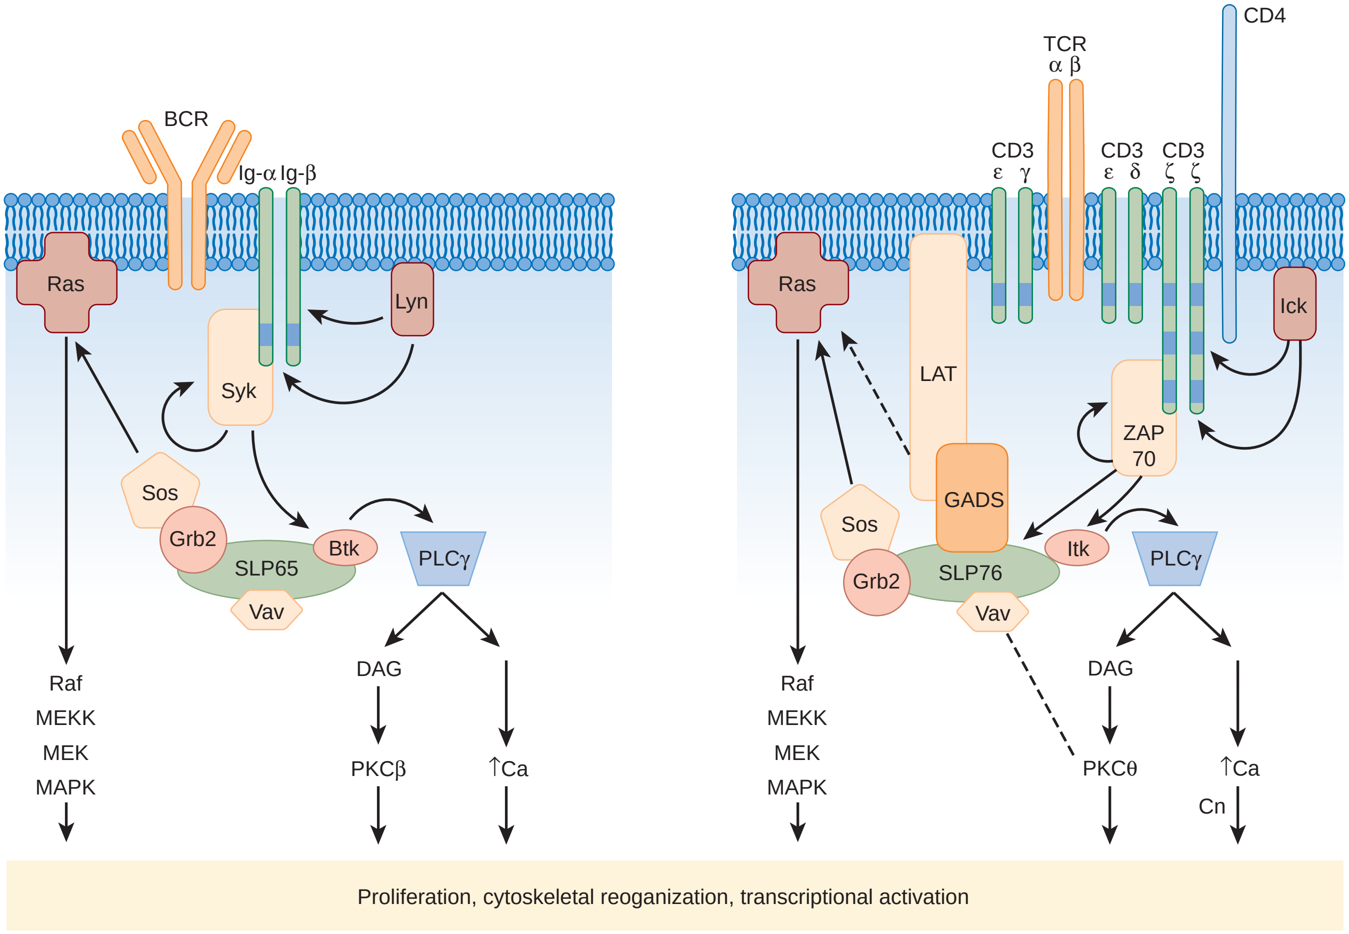

Figure 23-13 Schematic of B- and T-cell signaling pathways. Signaling cascades that emanate after engagement of antigen-specific receptors, the B-cell receptor (BCR) in B cells *(left)* and the T-cell receptor (TCR) in T cells *(right)*, are depicted. Each receptor has short cytoplasmic tails that do not themselves signal; the receptors signal instead via a complex of associated transmembrane molecules (Ig-α, Ig-β for B cells and the CD3 γ, δ, ε, and ζ proteins for T cells) that have immunoreceptor tyrosine–based activation motifs (ITAMs, depicted as *blue boxes*). Phosphorylation of ITAMs by early protein tyrosine kinases such as Lyn and Lck is critical for recruitment of Syk in B cells and ZAP70 in T cells, which go on to trigger the rest of the cascade. Adaptor proteins such as SLP65 and SLP76 nucleate a host of signaling molecules to activate Ras and protein kinase C (PKC) and increase intracellular calcium (Ca). The final effects of proliferation, cytoskeletal reorganization, and transcriptional activation ensue. B and T cells share a number of intermediates such as phospholipase C γ (PLCγ), Grb2, Sos, Ras, and Vav. Related molecules specific to B or T cells are depicted with similar shapes (e.g., SLP65/SLP76, Btk/Itk). *DAG,* Diacylglycerol; *MAPK,* mitogen-activated protein kinase; *MEK,* MAPK kinase; *MEKK,* MEK kinase.

to SLP65 by way of the SH2 and Src homology 3 (SH3) domains and to the membrane by the Pleckstrin homology (PH) domain activates Btk.[192] The critical nature of Btk activation in BCR signaling is underscored again by its role as the gene responsible for X-linked agammaglobulinemia. Btk in turn activates an isoform of phospholipase C (PLCγ2) that hydrolyzes inositol phosphates to generate diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). DAG activates both an isoform of PKC (PKCβ) and Ras, whereas IP_3 induces an increase in intracellular calcium. Recruitment of Sos by way of the adaptor protein Grb2 also activates the Ras pathway, as does Vav, a guanine nucleotide exchange factor for Rac. Together, activation of these three pathways then triggers activation of mitogen-activated protein kinases (MAPKs); reorganization of the actin cytoskeleton; and nuclear translocation of critical transcriptional activators, including the NF-κB family, that promote survival and clonal expansion (see Fig. 23-13).[189,191]

Coreceptors Involved in B-Cell Activation

Three important coreceptors for B-cell activation are CD21 (also called complement receptor 2 [CR2]), CD19, and CD81. Antigens derived from bacteria or other extracellular microorganisms are more efficiently cleared when opsonized or bound by complement components, a mechanism that links the early innate immune response elicited by activation of complement to the adaptive humoral B-cell response. Binding of C3b to CD21 coclusters CD21, CD19, and CD81 with the BCR within lipid rafts.[179,187,193] Phosphorylation of CD19 by proximity to the activated BCR complex in turn generates docking sites for phosphatidylinositol 3'-kinase (PI3K), for Vav, and for Lyn. PI3K generates phospholipid intermediates that recruit Btk, as described earlier. Vav activates Rac, thereby activating MAPKs and inducing cytoskeletal reorganization. The response to opsonized antigens recognized by the BCR via its specific epitope is thus greatly enhanced by the binding of C3b to CD21.[194] CD81 appears to function primarily as an adaptor and is critically required for BCR and CD21/CD19 to associate with lipid rafts.[195,196]

Stimulation by way of the antigen receptor alone is insufficient to activate B or T cells, and, in fact, binding of receptor-ligand pairs between B and T cells is critical for activation of both. Many costimulatory pathways are shared between B and T cells and are discussed further later; binding of CD40 to its ligand CD40L (CD154) is the most crucial of these pathways for B-cell activation. CD40 is a 48-kd member of the TNF receptor superfamily that is expressed on B cells and other APCs constitutively, whereas CD40L is a 33-kd transmembrane protein with homology to TNF upregulated on activated CD4+ T cells. CD40/CD40L binding has been shown to be essential for B-cell growth and differentiation.[197] In vitro stimulation of B cells by cross-linking by way of monoclonal antibodies is sufficient to promote growth and class switching and is synergized by BCR stimulation or treatment with IL-4, or both. Engagement of CD40 with trimeric CD40L and clustering of the cytoplasmic tails lead to recruitment of a class of adaptor proteins, the TNF receptor–associated factors (TRAFs), which in turn activate a variety of kinases that ultimately culminates in activation of MAPK and NF-κB.[198] In addition to clonal expansion and survival, CD40 signaling also leads to upregulation of other costimulatory molecules such as CD80 (B7) and CD54 (intercellular adhesion molecule 1 [ICAM-1]).[198]

The relatively recently discovered TLR can trigger B-cell activation alone (see earlier discussion) and also can serve a costimulatory function with BCR signals.[175,199] At least 11 TLRs in humans have been found, each recognizing different microbial components, such as LPS (via TLR4), peptidoglycan (TLR2), double-stranded RNA (TLR3), flagellin (TLR5), and CpG DNA (TLR9).[200] The response to intact microbes may involve recognition of microbial components simultaneously by the BCR and TLR, and interestingly, BCR-TLR co-recognition may play a role in the generation of autoantibodies.[201,202]

Follicular B-Cell Differentiation: the Germinal Center

Activation of B cells and differentiation into memory and plasma cells have become increasingly well understood in the context of cellular trafficking and the complex architecture of the specialized anatomic site, the GC.[203,204] B cells, a critical subset of CD4+ T cells (follicular helper T cells or T_{FH}), and specialized follicular dendritic cells (FDCs) must interact through costimulatory contact and soluble factors to generate a long-lasting humoral response.

In the early stages of infection, innate immune cells such as dendritic cells and macrophages capture antigen, migrate to lymph nodes, and present peptides in the cleft of class II MHC to CD4+ T cells. Simultaneously, naïve B cells that recognize the same pathogen can internalize complex protein particles by receptor-mediated internalization of Ig, with the protein fragments being broken down and displayed as peptides by class II MHC. Naïve B cells that encounter their cognate antigen and become activated then migrate through the T-cell zone and contact T cells stochastically during the journey.[205] When T and B cells that recognize the same antigen interact through TCR-MHC interactions, costimulatory signals, namely CD40-CD40L interactions, enhance the interaction and result in clonal expansion of both T and B cells. These activated "helped" B cells then travel to the follicle and infiltrate a network of FDCs. FDCs are thought to have a specialized function consisting of capture of immune complexes and simultaneous binding of FcR to antibody and complement receptor 3 (CR3) to components of complement.[206] The antigen component of the immune complex can then be displayed to passing B cells by way of the BCR. Activated B cells that recognize antigen displayed on FDCs proliferate rapidly after further costimulation by CD4+ T cells and become the centroblasts and centrocytes that form the GC.

The role of T_{FH} in this process has been increasingly elucidated in recent years.[207,208] These specialized CD4+ T cells were first identified on the basis of their expression of CXCR5, a receptor typically found on B cells that binds the B cell homing chemokine CXCL13.[209-211] They can be found in spleen, tonsil, and lymph node, optimally positioned in the B follicles where they function, and phenotypically similar cells circulate in the blood.[212,213] Functionally T_{FH} are the key contributors to B cell help in the secondary lymphoid organs by virtue of the high-level production of IL-21,[214] a pleiotropic cytokine that is critical for induction of class switching along with IL-4, and high surface expression of ICOS.[215-218] The development of T_{FH} depends on IL-21 itself and the master transcription factor BCL6, as further discussed in the section on helper T cell differentiation and function.[217,219,220]

Somatic hypermutation is thought to occur at the centroblast stage and further diversifies the overall antibody pool by introducing mutations in the V_H and V_L regions of Ig in B cells involved in a GC response.[221,222] Nucleotides are thought to be mutated in a somewhat random fashion, in both the rearranged and nonrearranged V regions, but ultimately survival of B cells that have undergone hypermutation is dictated by positive and negative selection based on the affinity of the expressed Ig. In other words, mutations that disrupt affinity to the antigen to which the animal is responding will be selected against, whereas those that enhance affinity will be selected for, hence the term *affinity maturation*.

Isotype or class switching is thought to occur at the centrocyte stage. Because all naïve B cells express IgM, a low-affinity antibody, inducing activated B cells to produce high-affinity IgG or IgA significantly enhances the functional humoral immune response to specific antigen at the time of infection and requires splicing of the V(D)J regions to the C_γ or C_α region. CD40-CD40L interactions are critical for this process, and T-cell–derived cytokines enhance class switching while influencing the Ig class or subclass.[223-225] In the mouse, T-B interactions in the context of interferon-γ (IFN-γ) tend to promote switching to IgG2a and IgG3, whereas IL-4 directs switching to IgG1 and IgE (see Table 23-2).

GC B cells then differentiate into either plasma cells or switched memory B cells. How GC B cells "choose" between the plasma cell and memory B-cell fate remains unclear.[226] Plasma cells are terminally differentiated B cells found primarily in bone marrow and are specialized for high-level secretion of IgG, IgM, and IgA. They have a

TABLE 23-2 Immunoglobulin Subclass Definition

Class	Isotype	Heavy Chain	Molecular Formula	Molecular Mass (kd)	Plasma Concentration (mg/mL)*	Cross Placenta	Fix Complement	Biologic Functions
IgG								Complement activation, opsonization for Fc receptor
	IgG1	γ1	$\gamma1_2\kappa_2$ $\gamma1_2\lambda_2$	150	7-9	+	+	Antitoxins, antibody to most bacterial antigens
	IgG2	γ2	$\gamma2_2\kappa_2$ $\gamma2_2\lambda_2$	150	2-3	+	+	Antipolysaccharide antibodies to bacterial capsules
	IgG3	γ3	$\gamma3_2\kappa_2$ $\gamma3_2\lambda_2$	150	0.7-1	+	+	Cytophilic antibodies (e.g., to Rh antigens)
	IgG4	γ4	$\gamma4_2\kappa_2$ $\gamma4_2\lambda_2$	150	0.3-0.5	+	–	Anticoagulants, such as anti–factor VIII in hemophiliacs
IgM		μ	$(\mu_2\kappa_2)_5$ $(\mu_2\lambda_2)_5$	950	1.5	–	+	Receptor in B-lymphocyte membrane, antibodies to lipopolysaccharides, complement activation, natural antibody
IgA				150 or 300				Present in external secretions, alternative complement activation (?)
	IgA1	α1	$\alpha1_2\kappa_2$ $\alpha1_2\lambda_2$		1-3	–	–	Virus-neutralizing antibody
	IgA2	α2	$(\alpha2_2\kappa_2)_2$		0.5-0.7	–	–	Principal secretory antibody
IgD		δ	$\delta_2\lambda_2$ $\delta_2\kappa_2$	180	0.3	–	–	Unknown, receptor in B lymphocyte membrane
IgE		ε	$\varepsilon_2\lambda_2$ $\varepsilon_2\kappa_2$	190	0.0005[†]	–	–	Anaphylactic antibodies or "reagins," binds to mast cells, mediator of release

*Plasma concentrations of the immunoglobulins vary significantly with age in pediatric populations. Adult norms are given here. IgG at birth reflects maternally transferred immunoglobulin and wanes over several months, with a nadir at approximately 4 months and rising thereafter as the infant's own production takes over. IgM and IgA levels rise with age during infancy and childhood.

[†] Usually expressed as international units; up to 200 IU is considered normal.

characteristic histologic appearance with so-called clockwork chromatin, eccentric nuclei, and markedly expanded endoplasmic reticulum and can be identified by expression of CD138 (also called syndecan-1). Class-switched memory B cells, which generally can be identified by virtue of the loss of IgD and gain of CD27 surface expression,[118] are able to circulate back to bone marrow and secondary lymphoid organs and, like memory T cells discussed later, are responsible for the rapid and effective anamnestic immune response characteristic of acquired immunity. A number of congenital deficiencies that affect T-cell–dependent B-cell maturation are characterized by a lack of GC formation and switched memory B cells; such conditions include CD40L deficiency (discussed later), X-linked lymphoproliferative disease (caused by mutation in SH2D1A or SLAM-associated protein [SAP]), and two molecules recently shown when mutated in humans to cause common variable immunodeficiency, ICOS (inducible T-cell costimulator) and TACI (transmembrane activator and calcium modulator and cyclophilin ligand interactor).[227-231] More recently, both somatic hypermutation and class switch recombination have been found to require a newly discovered activation-induced deaminase (AID) that deaminates deoxycytidine to form deoxyuridine; subsequent repair of the deoxyuracil-deoxyguanosine mismatch triggers nucleotide substitution or excision, thereby generating diversity and also joining VDJ regions to a different constant region class.[221,232] Humans born with defects in the *AID* gene have failure of both processes that results in a hyper-IgM phenotype.[233-235]

B-Cell Tolerance

Like T-cell tolerance (discussed later), B-cell tolerance is essential to prevent autoimmune reactions. Immature B cells can be made tolerant in the bone marrow to antigens expressed by the host (i.e., self-antigens) through clonal deletion.[236] If the surface IgM (sIgM) expressed on an immature B cell binds with high avidity to a self-antigen, the cell will be stimulated to undergo apoptosis, a form of cell death characterized by chromosomal fragmentation and membrane blebbing. The B cell may also undergo receptor editing, a process whereby that B cell's Ig gene will further rearrange to express a different, nonautoreactive Ig molecule.[78] The few B cells that escape central deletion may be rendered anergic in the periphery, a state in which the B cell expresses a gene that encodes a self-reactive antibody yet is unable to respond to antigen. The molecular mechanisms responsible for anergy are incompletely understood but may involve alternative signaling when the BCR is activated in the presence or absence of costimulation. For instance, BCR triggering in the context of concurrent TLR signaling (secondary to microbial products in addition to the BCR-specific antigen) leads to upregulation of CD86, which engages CD28 on T cells and recruits T-cell help. In the absence of TLR signals, the upregulation of CD86 is not sustained, and the BCR signals are attenuated.[237] A group of TNF and TNF receptor family members, including BAFF (also known as BLyS, *TNFSF13B*)[238] and APRIL (*TNFSF13A*),[239] whose receptors include TACI (*TNFRSF13B*, CD267),[240-242] BCMA (*TNFRSF17*, CD269)[240,242] and BAFF-R (*TNFRSF13C*, CD268),[243] have been shown to be important in B-cell homeostasis and autoimmunity. Interestingly, mice that overexpress BAFF exhibit autoimmunity,[244,245] and humans with a variety of rheumatologic diseases have been shown to have high BAFF serum levels.[246] The increasing use of rituximab, humanized anti-CD20 antibody, for the treatment of autoimmune disease and, recently, chronic graft-versus-host disease (GVHD) underscores the importance of dysregulated humoral immunity in human disease. More recently, a fully human IgG1-λ monoclonal antibody specific for BAFF/BLyS, belimumab, has been shown to have efficacy in systemic lupus erythematosus[247] and is approved by the U.S. Food and Drug Administration (FDA) for treatment of mild to moderate disease.

Function of Secreted Immunoglobulin

Secretion of a diverse repertoire of Ig is essential for protection of the host from infection and for neutralization of toxin. Once formed, binding of specific antibodies to microorganisms, virally infected cells, toxins, or other pathogens is essential for complement-mediated lysis, antibody-dependent cellular cytotoxicity (ADCC), opsonization, phagocytosis, and neutralization of toxins and viruses (see Table 23-2). Different heavy-chain isotypes perform different functions preferentially. IgM, IgG1, IgG2, and IgG3 activate the complement cascade, whereas only IgG1 and IgG3 bind effectively to phagocytic Fcγ receptors. IgE is able to bind to the Fcε receptors expressed on mast cells and eosinophils. In addition, secreted IgA antibodies play a role in protection from invasion through mucosal surfaces.

Different classes of antibodies not only have different functions but also predominate in different compartments in the body. IgA is predominantly secreted, IgM is primarily intravascular, and IgG is generally the major antibody found in tissues and peripheral blood. IgG is able to cross the placenta to provide some protective immunity to the fetus; passive protection from long-lived IgG molecules confers postnatal immunity. However, although the function and location of the antibody classes differ, subpopulations of B cells are able to migrate and home to specific regions of antigen presentation. Therefore generalized B-cell immunity may result from localized antigen presentation, as paradigmatically demonstrated by the efficacy of successful vaccination programs.

T-CELL ACTIVATION AND FUNCTION

CD4+ and CD8+ TCR αβ T cells exported from the thymus circulate in a naïve or resting state in the blood and lymphoid organs but are poised to be activated by cognate antigen presented by MHC on the surface of APCs. CD8+ cytolytic T cells induce the lysis of foreign cells, such as infected, malignant, or allogeneic cells.[67] CD4+ helper T cells interact with B cells via cell-cell and soluble factors to induce class switching and the generation of antigen-specific antibodies. They also provide "help" to CD8+ cytolytic T cells.[37,248] Activation of resting T cells not only relies on signaling cascades downstream of the TCR-MHC interaction (signal 1) but also requires or is enhanced by the binding of a variety of T-cell surface molecules to their ligands on APCs (signal 2). The lack of a second signal generally results in nonresponsiveness or anergy of the T cell and serves to ensure that activation of the naïve T cell is not only antigen specific but regulated as well. The affinity of the cognate antigen, the engagement of specific costimulatory molecules, and the cytokine milieu collectively influence and modulate the outcome of T-cell activation and thereby result in the generation of distinct effector cell subsets. Although most effector T cells perform their function and expire, a subset of activated cells differentiate into long-lived memory cells capable of rapid anamnestic responses.

T-Cell Receptor Triggering and Activation

The αβTCR is a multimeric transmembrane complex composed of a disulfide-linked antigen-binding clonotypic heterodimer in noncovalent association with the signal-transducing CD3 subunits (CD3εγ, CD3εδ, and CD3ζζ) (Fig. 23-14, *A*).[249,250] TCR signaling via CD3 dimers evokes T cell lineage commitment and repertoire selection during development, maintains the peripheral T cell pool, and further differentiates naïve T cells into effector or memory cell populations upon immune stimulation. Each CD3ε, γ, and δ subunit contains an extracellular Ig-like domain, a membrane-proximal stalk region, a transmembrane segment, and a cytoplasmic tail. The interaction between an αβ TCR heterodimer on the T cell and a pMHC ligand on an antigen-presenting cell (APC) initiates a cascade of downstream signaling events. These events are transmitted via the immunoreceptor tyrosine-based activation motif (ITAM) elements in the cytoplasmic tails of the associated CD3 subunits, whose lengths are substantial relative to those of the TCR α and β tails.[251,252,253,254] The various CD3 chains induce distinct patterns of cellular protein tyrosine phosphorylation on activation to recruit intracellular adaptors and signaling molecules. Early, intermediate, and late gene activation programs ensue.[255] Reviews such as Rudolph and colleagues[249] have focused on the structural nature of immune recognition involving Vα and Vβ domains of a given TCR and its pMHC ligand. How recognition of pMHC by a weakly interacting αβ TCR heterodimer on the T cell surface evokes intracellular signaling by way of the adjacent CD3 components of the TCR complex has remained undefined.

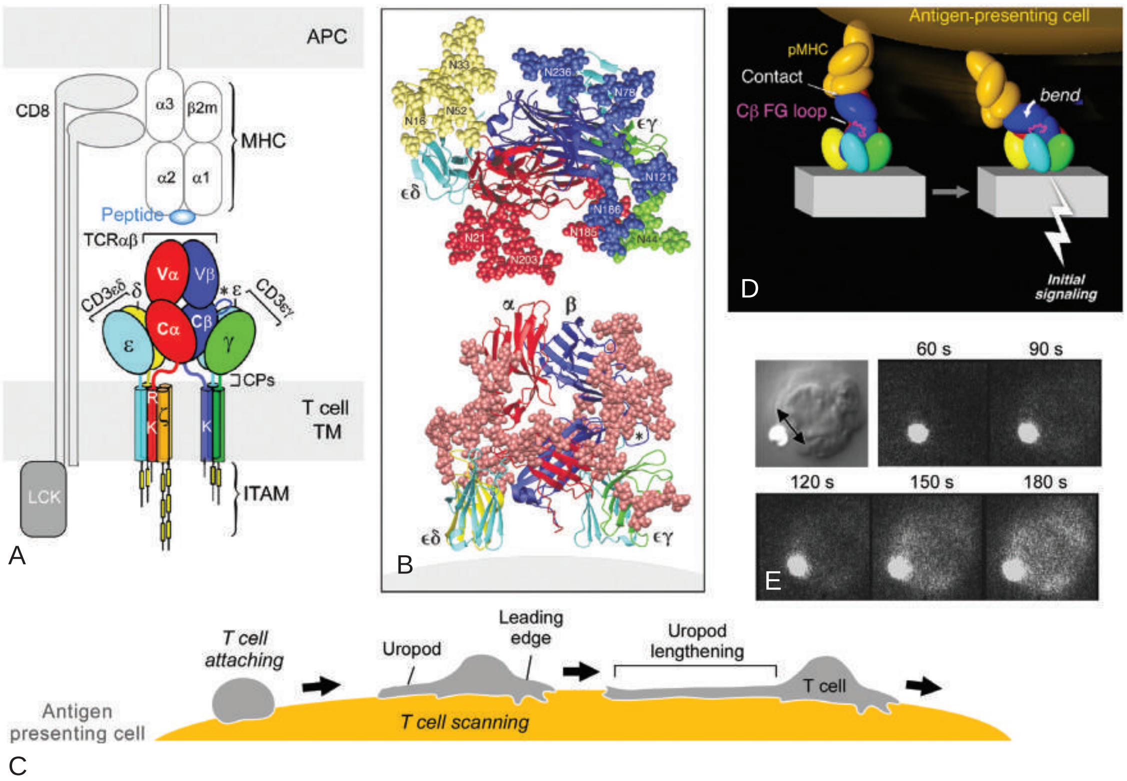

Figure 23-14 TCR complex interaction with pMHC and its activation by mechanical force. **A**, TCR components (ectodomains, stalk CP, TM, and cytoplasmic tails) are labeled and shown in distinct colors. The pMHC on the APC and the interacting CD8αβ heterodimer are not colorized. The relative positions of the positively charged residues in TCR α and β TMs are shown. For simplicity, putative interactions with CD3 acidic residues are not indicated. **B**, Ectodomain structure in ribbon form based on PDB code IFND, 1XMW, and 1JGJ is shown from the perspective of pMHC *(top)* and side *(bottom)* views with the position of T-cell membrane shown in the latter. In the *top* view, adducted glycans in CPK visualization are colored according to subunit, whereas all sugars are denoted in beige in the *side* view. The CB FG loop is labeled by an * in each panel. **C**, T-cell scanning an APC surface in search of specific pMHC. On attachment the TCR assumes a polarized morphology with a leading edge and lengthening uropod. **D**, One pMHC molecule is shown in orange on the APC, whereas the ectodomains of TCR subunits on the T cell membrane below are colored as in **A**. The view is from the CD3εγ side. Initial ligation of the TCR by pMHC *(left)* constitutes a detachable mechanosensor that, as a result of continued T cell scanning, transmits an external torque (bend) into initial signaling (bolt) via the rigid components of the TCR complex before dissociation. The CB FG loop is shown in magenta. **E**, Calcium flux in naïve T cells after application of external mechanical force (low piconewtons) using optical tweezers. 10 to 100 pMHC copies per polystyrene bead are used in such experiments. The white sphere represents the specific pMHC loaded polystyrene bead. Increase in intracellular free calcium is evident from the increase in immunofluorescence of the calcium orange loaded cells. The time intervals after force application are given in the fluorescent images, and the direction of external mechanical force is denoted by the *double-headed arrow* in the bright field image.

Functional TCR αβ heterodimers were first identified by mAbs on antigen-specific T cell clones and then T cell hybridomas.[256,257,258,259] Subsequent sequence analysis of TCRs predicted that they would share with antibodies a common structural basis of ligand recognition, akin to an antibody Fab fragment.[260,261] These results agreed with peptide mapping studies of α and β subunits that identified conserved as well as variable peptides, implying the existence of constant and variable domains in the TCR α and β subunits. The biochemical results were later confirmed and extended by DNA cloning [262,263] and elegantly delineated further by the crystal structure of an intact murine αβ TCR[264] and a complex between a human TCR, viral peptide, and human MHCI molecule that followed.[265]

As noted previously, structures of TCR αβ heterodimers and antibody Fab fragments seem very similar (see Fig. 23-7). While each of the four TCR α and β domains, like those of Fab, has been assigned an Ig fold, deviations are notable in both TCR constant domains[79,263,264] as well as in the Vα domain.[266] These deviations define fundamental differences between the TCR as a cell surface receptor and antibody as a soluble immune molecule. First noted on structural analysis was the striking elongation of the FG loop of the Cβ domain connecting its F and G β-strands. Unlike other Ig-like structures, there is a 13 amino acid (aa) insertion within the FG loop.[267] Figure 23-7, *A* shows a side view of the crystallographically resolved murine N15 MHCI-restricted αβ TCR.[268] The unique protrusion of the Cβ domain's FG loop is apparent (labeled). Despite its length, the FG loop is internally well-structured, and constitutes an integrated component of a rigid structural entity that connects the Vβ and Cβ domains.[268] This feature of the FG loop is conserved in αβ TCRs among all mammalian species studied to date, having co-evolved with the development of distinct CD3γ and CD3δ genes.[269] Consistent with the importance implied by this conservation, removal of the FG loop

(ΔFG) in T cell transfectants as well as TCRs displayed on naïve T cells by transgenesis,[270,271] diminishes T cell activation and alters development. Second, the overall shape of the TCR C domain module was observed to be remarkably asymmetric. Third, unlike Fabs, the αβ TCR heterodimers are heavily N-linked glycosylated (Fig. 23-14, *B*). Such adducts can dynamically modify TCR function.

A model of the TCR complex of αβ, CD3εγ, and CD3εδ ectomains[272] defines a plausible topology and emphasizes its glycan richness (see Fig. 23-14, *B*). Given that CD3ζ has an ectosegment that is only 9 amino acid long, its extracellular segment is omitted from the figure as are the connecting peptides (CPs) of the TCR α and β chains and the stalk regions of CD3ε, CD3γ, and CD3δ. The multiple N-linked glycan adducts of the TCR complex (Fig. 23-14, *B, top panel*) help guide pMHC ligands to the TCR recognition surface, reducing entropic penalties by directing binding to the exposed, glycan-free CDR loops. It is important to note that glycans are large and dynamic. These adducts can affect movement of the TCR subunits, thereby affecting signaling. Immediately evident in Figure 23-14, *B* is the central position of the TCR αβ heterodimer with a vertical dimension of 80Å projecting from the cell membrane, flanked on either side by the shorter (40Å) squat and rigid CD3 heterodimers, CD3εδ on the “left” TCRα side and CD3εγ on the “right” TCRβ side.

As T cells perform immune surveillance by scanning APCs in search of antigenic peptide/MHC complexes (pMHC) (Fig. 23-14, *C*), ligation of a TCR by pMHC will bend the TCRαβ heterodimer and thereby push on CD3 components by way of the FG loop among other structural elements before a stop-movement signal (Fig. 23-14, *D*). Recent data using optical tweezers show that the TCR is activated by force (Fig. 23-14, *E*).[273] Mechanotransduction makes T-cell triggering extremely sensitive, accounting for the small number of pMHC complexes per APC required to activate T cells.[274] Precedent for mechanoreceptors in the hematopoietic system is the von Willebrand factor (VWF) receptor on platelets where tensile stress on bonds between the GPIbα subunit and the VWFA1 domain under fluid dynamic conditions triggers integrin $\alpha_{IIb}\beta_{III}$ activation to support platelet adhesion.[275,276]

The physical force relayed from the ectodomain onto the TM during mechanosensor function may be transmitted to the cytoplasmic tail directly or indirectly (or both) by modification of the membrane lipid organization.[277,278] The CD3ε cytoplasmic tail maintains close interaction with the plasma membrane via basic CD3ε residues and acidic phospholipids enriched in the inner leaflet of the plasma membrane.[279,280] Two key tyrosine residues in the CD3ε ITAM are deeply inserted in the hydrophobic core of the lipid bilayer. Release of sequestered tyrosines must occur for phosphorylation by lck to follow. CD3ζ phosphorylation is also lipid dependent,[281] and the importance of the six ITAMs in the ζζ homodimer for signaling must not be underestimated.[251]

Our understanding of the signaling cascades downstream of the TCR has become increasingly complete and complex. Five major signal transduction pathways are triggered by TCR engagement: phosphotyrosine kinase (PTK) activation, plasma membrane phosphatidylinositol hydrolysis, changes in intracellular calcium concentration $[Ca^{2}+]_{i}$, RAS/MAPK, and PKC pathways (see Fig. 23-13). In recent years a variety of adaptor molecules and other families of proteins, including small Rho guanosine triphosphatases (GTPases), have been implicated in these pathways. Thus there is much crosstalk between the main pathways, which then converge on the activation of nuclear transcription factors critical for the expression of T-cell effector molecules, namely the cytokine genes, particularly IL-2. Finally, the spatial organization of the TCR signaling complex in ordered lipid microdomains, in which an “immune synapse” is formed at the point of contact between the T cell and APC, is thought to enhance T cell–APC interaction and allow directed secretion of cytokines locally to the contacting APC (Fig. 23-15).[282,283]

TCR activation leads to stop movement and formation of the immunologic synapse. Mechanoreceptor function is most likely additionally tunable by inducible actin cytoskeletal interactions with TCR and pMHC on T cells and APCs, respectively, because torque will be greatest in their presence. Within the synapse, force could be generated on the TCR by way of microcluster formation and actin-based trafficking.[284] Mechanosensing can be further amplified at the synapse where intermembrane distances (~150Å) are optimal for TCR/pMHC ligation in conjunction with other signaling molecules to sustain activation from both p-SMAC and c-SMAC components. The facilitating roles of adhesion molecules and CD4 and CD8 coreceptors have been discussed.[273] Rapid transport of TCRs to the immunologic synapse and TCR signaling after disengagement of pMHC likely give rise to serial TCR triggering for high activation efficiency within the immunologic synapse. In this dynamic mechanosensor model, signaling occurs by way of the built-in geometry of the TCR-pMHC complex.

Within seconds to minutes of TCR engagement, PTKs such as Lck and Fyn are activated and phosphorylate the ITAMs on CD3 subunits, particularly CD3 ζ (see Fig. 23-13). The physical association of Lck with the CD4 and CD8 coreceptor molecules, recruitment to the membrane by myristoylation and other modifications, and the multiplicity of Lck molecules in close proximity when the TCR-coreceptor complex is triggered are thought to promote and amplify its rapid activation.[285] Phosphorylated ITAM on CD3 ζ in turn recruits ZAP70, a 70-kd protein kinase whose homolog in B cells is Syk, via the phosphotyrosine-binding SH2 domain.[286] ZAP70 is phosphorylated by Lck, is activated, and then phosphorylates two key substrates, LAT (linker for activation of T cells) and SLP76 (SH2 domain–containing leukocyte protein of 76 kd). A host of downstream proteins, including Grb2, SOS, ITK, PLCγ, GADS, and VAV1, then converge on LAT and SLP76 to activate the phosphoinositol, calcium, and RAS/MAPK pathways.[190]

Recruitment of PLCγ to LAT and SLP76 catalyzes the hydrolysis of phosphatidylinositol 4,5-biphosphate to generate IP_3 and DAG, which in turn promote the increase in $[Ca^{2}+]_{i}$ and activation of the T-cell–specific isoform

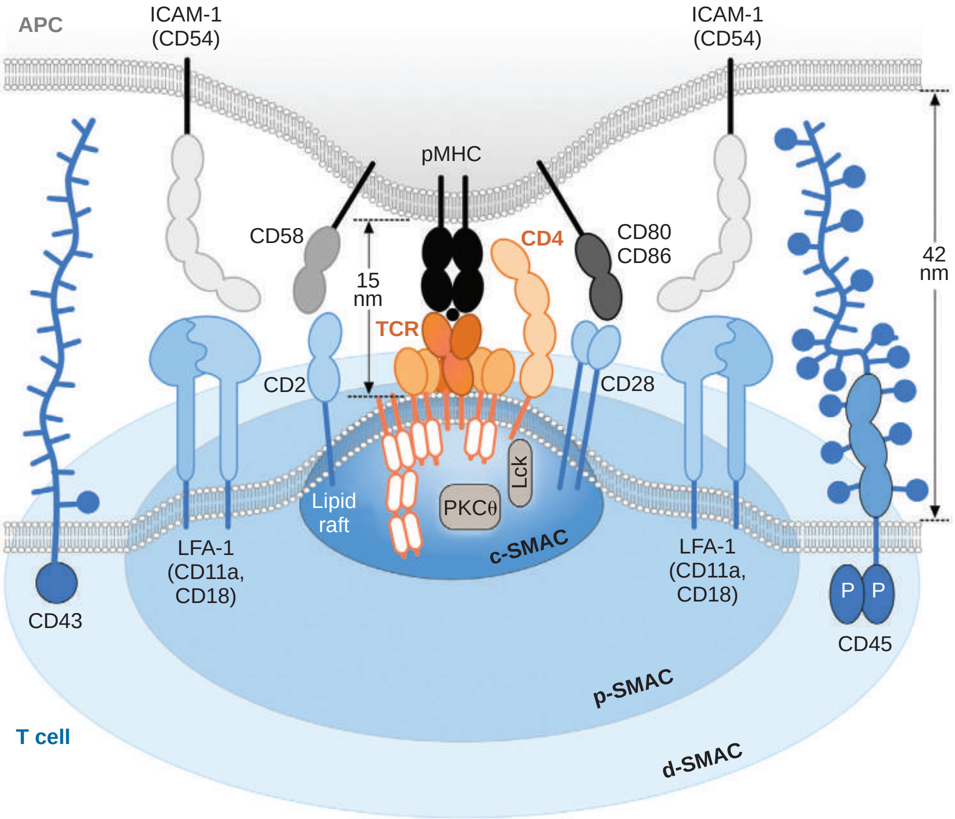

Figure 23-15 Immunologic synapse between a T cell and an antigen-presenting cell. The immunologic synapse is divided into central-supermolecular activation cluster (c-SMAC), peripheral-(p)-SMAC, and distal-(d)-SMAC in the *vertical view* provided. The alignment of receptors and adhesion molecules are ordered according to size. Membrane-membrane distance of approximately 15 nanometers (150Å) in the c-SMAC and 42 nanometers in the d-SMAC.[311,474-476] *(Modified from Yokosuka T, Saito T: The immunological synapse, TCR microclusters, and T cell activation.* Curr Top Microbiol Immunol *340:81–107, 2010.)*

PKCθ, respectively (see Fig. 23-13).[287,288] The critical downstream effect of the rise in $[Ca^2+]_i$ is activation of the calcium- and calmodulin-dependent serine/threonine phosphatase calcineurin, whose key direct substrates in T cells are members of the NF-AT family.[289-291] Dephosphorylation of NF-AT allows its translocation from the cytoplasm to the nucleus, where it binds, often in the presence of AP-1 elements, to the transcriptional regulatory sequences of *IL2* and other cytokine genes. The immunosuppressant agents cyclosporine and tacrolimus (FK506) function by forming macromolecular complexes with intracellular binding proteins (cyclophilins and FK-binding proteins [FKBPs], respectively), which in turn inhibit the phosphatase activity of calcineurin, thereby abrogating the early cytokine elaboration critical for T-cell expansion and function.[290,292,293]

Activation of the RAS pathway primarily occurs by the recruitment of the adaptor proteins Grb2 and Shc to phosphorylated LAT, which leads to recruitment of the guanine nucleotide exchange protein Sos (see Fig. 23-13). Sos catalyzes the conversion of inactive guanosine diphosphate (GDP)–bound RAS to active GTP-bound RAS and activates a series of MAPKs.[294] Activation of PKCθ in response to PLCγ described earlier can crosstalk with this pathway and induce increases in RAS and MAPK activity, although the mechanisms and relative contributions are still unclear. Major downstream effects of PKCθ activation include stimulation of AP-1 nuclear activity, regulation of JNK (the upstream kinase of AP-1), and activation of NF-κB.[287] Induction of these and other transcription factors, which cooperate with NF-AT translocation in response to rises in $[Ca^2+]_i$, strongly stimulates production of IL-2.

The transcriptional program executed in response to TCR stimulation includes the major T-cell cytokine IL-2; other cytokines, including IFN-γ and IL-4, the canonic T-helper type 1 and type 2 cytokines (discussed later); proliferative factors, including c-myc and c-fos; a variety of activation markers such as CD69, CD45RO, CD44; and growth factor receptors, most prominently the high-affinity IL-2 receptor subunit IL2Rα, also called CD25.[255] Binding of IL-2 to its receptor, in both autocrine and paracrine fashion, results in a growth factor–induced signal to the cell and induces the transition from G_1 to S phase of the cell cycle.[295,296,297,298] Interestingly, in recent years CD25 has been found not only to mark activated T cells but also to be expressed on naturally occurring T-regulatory cells, discussed later. The role of IL-2 in expanding activated effector cells and simultaneously its requirement for development and maintenance of the T-regulatory population result in pleiotropic effects of IL-2 in vivo and has complicated the potential use of IL-2 in the clinical setting.[299] However, recently a trial of IL-2 monotherapy has been successful in the treatment of steroid-refractory chronic GVHD, associated with expansion of regulatory T cells.[300] The high-affinity IL-2 receptor is composed of IL-2Rα (*IL2RA*, CD25), IL-2Rβ (*IL2RB*, CD122), and IL2Rγ (*IL2RG*, γ_c, CD132), this last a common signaling component of the cytokine receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. Mutations in the *IL2RG* gene[301,302] and the downstream factor *JAK3* (Janus kinase 3)[303,304] result in X-linked and autosomal recessive forms of SCID, respectively. In contrast to the inhibition of early signals downstream of $[Ca^2+]_i$ by cyclosporine and tacrolimus, the late proliferative response of T cells to binding of IL-2 to its receptor are abrogated by the immunosuppressant sirolimus (rapamycin), which complexes with FKBP to inhibit mTOR (mammalian target of rapamycin).[305] All three of these agents have been used in the prevention and treatment of GVHD and solid organ-graft rejection, and the actions of calcineurin inhibitors and rapamycin on serial events in T-cell activation have encouraged their use in combination therapy. Monoclonal antibodies directed against the IL-2Rα protein such as basiliximab and daclizumab have been approved for prevention of rejection of renal allografts, and their use is being explored for treatment of multiple sclerosis and GVHD.[306,307]

Coreceptors Involved in T-Cell Activation and the Immune Synapse

Because the affinity of the TCR for cognate antigen–MHC complexes and the density of TCRs on the naïve T cell are both relatively low, activation of the T cell depends on augmentation of the TCR signal by a complex combination of TCR-associated coreceptors, adhesion molecules, and other costimulatory molecules that transduce distinct signals. Spatial separation of kinases and phosphatases facilitates activation (see Fig. 23-15). Recent techniques that visualize the distribution of TCR and these affiliated molecules in relation to the site of T cell–APC contact have led to a model in which the immune synapse segregates into central, peripheral, and distal supramolecular activation clusters (c-SMAC, p-SMAC, and d-SMAC, respectively). The functional relevance of different synapse morphologies and the dynamics of formation and disassembly of the synapse are actively being investigated.[308,309,310,311]

The CD4 and CD8 glycoprotein coreceptors bind to class II and class I MHC molecules, respectively, and are used to classify T cells into helper and cytolytic subtypes.[37] The proximity of CD4 and CD8 coreceptors to the TCR-pMHC complex via bidentate interaction of pMHC with TCR and coreceptor[34] and the association of both CD4 and CD8 intracellular domains with the Src family tyrosine kinase p56lck bring p56lck into close association with its target CD3 ζ.[312,313] CD4 and CD8 coreceptors are generally found in the c-SMAC with TCR.

CD2 is a T-cell–specific glycoprotein receptor that binds to several ligands on the APC, including CD58 (LFA-3) and CD48 (see Fig. 23-15). Binding of CD2 to its ligand on the APC serves to improve adhesion and the strength of the TCR-pMHC interaction as well as membrane-membrane distances for optimal TCR-pMHC interaction.

CD45, also known as *leukocyte common antigen*, is a phosphotyrosine phosphatase. It is generally excluded from the immune synapse in a manner that suggests that the size of the ectodomain of a given receptor determines its presence or absence in the synapse.[282] The major substrate of CD45 is thought to be p56lck, as well as possibly JAK/STATs, CD3 ζ, and ZAP70[314]; it is suggested that the dynamic repositioning of CD45 during synapse formation and disruption alters its substrate specificity.[315] Deficiency of CD45 has been studied in mice and humans and results in defects in thymic T-cell development, T-cell function, and autoimmunity.[314,316,317] Alternative splicing of the CD45 message results in multiple isoforms, most notably CD45RA, expressed in naïve or resting T cells, and CD45RO, characteristic of activated or previously activated T cells.[318]

Costimulation of T Cells

TCR ligation (signal 1), even in the presence of CD4 or CD8 engagement, is insufficient for activation of resting T cells. In the absence of appropriate costimulation, TCR occupancy alone can result in T-cell unresponsiveness (T-cell clonal anergy, ignorance, or tolerance) on subsequent exposure to antigen. Tolerance is characterized by the inability to proliferate or secrete cytokines in response to secondary stimulation by the same antigen. Anergy is classically defined as this same failure, but it can be rescued or reversed by exogenous IL-2 in vitro.[319] Costimulation (signal 2) typically is mediated by receptors on T cells recognizing ligands on activated APCs (see Fig. 23-15).

CD28 (*CD28*), the first discovered costimulatory molecule that prevents the induction of anergy, is the original defined member of a family of related molecules. Human CD28, a homodimer of two 44-kd glycoproteins, is expressed on essentially all CD4+ cells and approximately 50% of CD8+ cells. CD28 interacts with the B7 family members CD80 (*CD80*, B7-1) and CD86 (*CD86*, B7-2). Interaction of CD28 with CD80 or CD86 increases, quantitatively, the amount of IL-2 produced by both transcriptional and post transcriptional mechanisms,[320] augments T-cell proliferative responses, and enhances T-cell survival by induction of the anti-apoptotic protein Bcl-X_L.[321] Notably, CD28-dependent costimulation appears to be resistant to inhibition by the immunosuppressants cyclosporine and tacrolimus (FK506), inhibitors of the serine/threonine phosphatase calcineurin, thus suggesting that this pathway uses a different cascade of biochemical signals than the calcineurin-sensitive TCR complex.[322-324]

Structurally similar to CD28, CD152 (cytotoxic T-lymphocyte antigen 4, *CTLA4*) is another CD28 family member that also binds to CD80 and CD86. CD152 is expressed only minimally on resting T cells but is induced on recently activated T cells. Mice rendered genetically deficient in *Ctla4* expression die postnatally with progressive lymphoproliferation[325,326]; it is now clear that the endogenous function of CD152 is to downregulate T-cell activation to terminate T-cell responses.[322,327]

TABLE 23-3 Stimulatory Molecules

Receptor	Expression	Ligand	Expression	Major Effect of Engagement
CD28	CD4 T cells, CD8 T cells (50%)	CD80, CD86	Dendritic cells, B cells, monocytes, T cells	Activating
CTLA4	Activated T cells	CD80, CD86	Dendritic cells, B cells, monocytes, T cells	Inhibitory
ICOS	Thymocytes, activated T cells	ICOSLG	Dendritic cells, B cells, monocytes, T cells, fibroblasts, endothelial, epithelial	Activating
PD-1	Activated T and B cells, myeloid cells	PD-L1, PD-L2	Dendritic cells, B cells, monocytes, T cells, tissues, tumors (PD-L1); dendritic cells, monocytes, some B cell lymphomas (PD-L2)	Inhibitory
Unknown		B7-H3	Dendritic cells, B cells, monocytes, T cells, NK cells, bone marrow	Unknown
CD27	T cells, some B cells, some NK cells, hematopoietic progenitors	CD70	Dendritic cells, B cells, T cells, NK cells, mast cells, smooth muscle, thymic epithelium	Activating
OX40	Activated T Cells, NK cells, neutrophils	OX40L	Dendritic cells, B cells, monocytes, T cells, NK cells, mast cells, endothelium, smooth muscle	Activating
4-1BB	Activated T cells, NK cells, mast cells, neutrophils	4-1BBL	Dendritic cells, B cells, monocytes, T cells, NK cells, bone marrow mast cells, smooth muscle cells	

CTLA-4, Cytotoxic T-lymphocyte antigen 4; *ICOS,* inducible T-cell costimulator; *NK,* natural killer; *PD-1,* programmed death 1.

CD278 (inducible costimulator [*ICOS*]) is another member of the CD28 family that was cloned by generating monoclonal antibodies directed against activated T cells.[328] Like CD152, ICOS is expressed on activated T cells. ICOS does not bind CD80 or CD86 but instead binds to a novel, TNF-α–inducible adhesion molecule, CD275 (inducible costimulator ligand [*ICOSLG*], B7h, B7-H2, B7RP-1).[329] Signicantly, engagement of ICOS appears to affect T-helper differentiation by favoring IL-10 and IFN-γ production (discussed later). Studies of deficient mice and humans with *ICOS* mutation demonstrate its critical role in T-cell help, normal humoral responses, and B-cell heavy-class switching.[229,330-332]

The number of CD28/B7 family members that function as costimulatory molecules continues to grow (Table 23-3). Expressed on thymocytes and activated immune cells, programmed death 1 (PD-1) is a CD152-like molecule that also functions as an important negative regulator of immune responses.[333-335] An autoimmune disorder resembling systemic lupus erythematosus develops in PD-1–deficient mice. The molecular mechanism of negative regulation by PD-1, like that by CD152, appears to be recruitment of a phosphotyrosine phosphatase (SHP-2) to the signaling receptor.[336] Two PD-1 ligands have been isolated; both are posited to play a role in the induction and maintenance of peripheral tolerance.[333,337,338] Finally, B7-H3, a distinct B7 family member important for costimulation of IFN-γ production, has been isolated[339]; B7-H3 binds a counter-receptor on activated T cells distinct from any CD28 family member heretofore characterized.

In addition to CD28/B7 family members, members of the TNF family function as important modulators of T-cell effector and T-cell–dependent B-cell responses. Interaction of CD154 (*CD40LG*) with CD40 is essential for B-cell activation, Ig production, and heavy-chain isotype differentiation, as discussed earlier. The interaction of CD154 with CD40 also upregulates CD80 expression on APCs and is thus important for sustaining a T-helper precursor cell (T_H1) response.[340] X-linked hyper-IgM syndrome is an autosomal recessive disorder characterized by a deficiency of CD4+ T-cell function and T-cell–dependent antibody responses; it is caused by mutation in the *CD40LG* gene located on human chromosome X.[341] Affected patients have normal or increased IgM levels and very low to undetectable IgG and IgA levels and are susceptible to opportunistic infections such as *Pneumocystis jiroveci* because of intrinsic CD4□ T-helper dysfunction.[342,343] Allogeneic stem cell transplantation offers a curative therapy for patients with an appropriate donor.[344] Murine models of X-linked hyper-IgM syndrome have been developed by genetic disruption of either the *Cd40* or *Cd40lg* genes, which mimics the phenotype of the human disorder.[345-348]

Other TNF family molecules that are important for modulating the T cell response include CD27 *(TNFRSF7)*, CD134 (OX40, *TNFRSF4*), and CD137 (4-1BB, *TNFRSF9*). All of these molecules are inducible on activated T cells. CD70 (CD27L, *TNFSF7*), a protein of approximately 50 kd that is transiently expressed on recently activated T and B lymphocytes, binds CD27, a homodimer expressed on the surface of naïve CD4+ and CD8+ T cells.[349,350] CD27/CD70 interactions promote TNF-α but not IL-2 production from T cells, as well as expression of CD154 on the T-cell surface. This receptor-ligand interaction also appears to induce B-cell terminal differentiation to plasma cells.[117] Expression of CD134 (OX40, *TNFRSF4*), a glycoprotein of approximately 48 kd, depends on TCR signaling on CD4+ activated cells and binds its ligand CD252 (OX40L, *TNFSF4*) which is expressed on lymphocytes, APCs, and also endothelium and smooth muscle.[351] CD134/CD252 engagement enhances T-cell proliferation and cytokine production at limiting antigenic densities, enhances B-cell and dendritic cell function, and modulates T-cell migration to B-cell follicular areas.[352,353] Thus CD134/CD252 interactions have been suggested to prolong and enhance clonal expansion and immune responses at sites of infection and inflammation. 4-1BB[354-357] is a transmembrane glycoprotein whose expression is induced on T cells after activation and binds to its ligand CD137L (4-1BBL, *TNFSF9*), which has an expression pattern similar to that of OX40L.[351] All these TNF family ligand-receptor pairs share a common signaling pathway via the TNF receptor–associated factors (TRAFs), which bind IκBα and activate the NF-κB pathway.[351] These receptors serve to enhance T cell survival, proliferation, and cytokine production; modulate the inflammatory milieu through cytokine production by APCs; and affect B-cell proliferation and antibody production.[351] The potential effect of blockade or neutralization of OX40 or 4-1BB is complicated to predict given that these receptors are also expressed on regulatory T cells, with some studies showing inhibition and others showing enhancement of regulatory T-cell generation or survival.[351]

Manipulation of T cell stimulation by soluble receptors, ligands, or antibody-mediated blockade is of increasing interest in the treatment of autoimmunity, cancer, and solid organ rejection.[358-360] More recently, the discovery that regulatory T cells (discussed later) are also exquisitely sensitive to costimulatory signals has complicated the potential outcome of such therapeutics. The pleiotropic effects in vivo of our current armamentarium are underscored by the sobering case of six patients in England who suffered life-threatening cytokine storm within hours of receiving an anti-CD28 antibody agonist intended to expand regulatory T cells.[361] Nevertheless, progress has been made in that blockade of costimulation with CTLA4-IgG1 (abatacept; see Table 23-4) has been approved for use in rheumatoid arthritis and juvenile inflammatory arthritis,[362,363] and its use is being explored in other settings.

TABLE 23-4 Selected Monoclonal Antibodies and Fusion Proteins in Therapeutic Use for Treatment of Autoimmune or Inflammatory Disease, or Transplantation

Generic Name*	Trade Name	Type	Target	Approved Use
natalizumab	Tysabri	Humanized mAb	α4 integrin	Multiple sclerosis, Crohn disease
belimumab	Benlysta	Human mAb	BAFF (BLys)	Systemic lupus erythomatosus
rituximab	Rituxan	Chimeric human mAb	CD20	Refractory rheumatoid arthritis
ofatumumab	Arzerra	Human mAb	CD20 membrane proximal epitope	Rheumatoid arthritis
epratuzumab	Lymphocide	Humanized mAb	CD22	Systemic lupus erythromatosus, Sjogren disease
daclizumab	Zenapax	Humanized mAb	CD25	Transplant rejection
basiliximab	Simulect	Chimeric mAb	CD25	Transplant rejection
ipilimumab		Human mAb	CTLA4	Melanoma
abatacept	Orencia	CTLA4 extracellular domain-IgG1 Fc fusion protein	CTLA4	Rheumatoid arthritis refractory to TNF blockade
anakinra	Kineret	IL1RA	IL-1	Rheumatoid arthritis
tocilizumab	Actemra	Chimeric mAb	IL6R	Rheumatoid arthritis
infliximab	Remicade	Chimeric human mAb	TNFα	Psoriasis, Crohn disease, ankylosing spondylitis, psoriatic arthritis, rheumatoid arthritis, ulcerative colitis
etanercept	Enbrel	TNF receptor 2-IgG1 Fc fusion protein	TNFα	Psoriasis, ankylosing spondylitis, psoriatic arthritis, rheumatoid arthritis
adalimumab	Humira	Human mAb	TNFα	Psoriasis, Crohn disease, ankylosing spondylitis, psoriatic arthritis, rheumatoid arthritis, juvenile idiopathic arthritis, ulcerative colitis

TNF, Tumor necrosis factor.

*The nomenclature of monoclonal antibodies has evolved to denote the origin of the variable and constant regions. The suffix *mab* denotes a monoclonal antibody. Antibodies that are fully murine have *mo* immediately preceding *mab*. Antibodies in which the constant regions have been replaced with human are denoted as chimeric with *xi* immediately preceding *mab*. Antibodies in which the constant regions and part of the variable regions have been replaced with human are denoted as humanized with *zu* immediately preceding *mab*. Finally antibodies that are fully human with no murine elements are denoted with *u* immediately preceding *mab*.

Progress in the understanding of T-cell stimulation and activation with regard to intracellular signaling has been further exploited to engineer T cells directed against cancer cells, bearing so-called *chimeric antigen receptors* (CARs).[364,365] CARs are fusion receptors in which the specificity resides in single-chain variable fragments (scFv) from monoclonal antibodies directed against a tumor antigen of choice, and the signaling domains are derived from components of the T-cell receptor signaling machinery. The first such molecule used the CD3 ζ signaling domain.[366] These fusion receptors have some key advantages, including that specificity does not require presentation via MHC, that scFv with the appropriate avidity can be chosen or designed, and that CARs do not pair with TCR or compete with TCR for CD3 chains. That CARs can only be directed against cell surface proteins is a significant disadvantage insofar as it obviously limits the tumor antigens that can be targeted. Many technical hurdles must be overcome to make CARs safe and effective, including efficient transduction into human T cells, adjustment of the size of the spacer between scFv moiety and transmembrane region to optimize avidity,[367,368] addition of signaling domains beyond CD3 ζ alone to improve function,[369-371] and persistence of CAR bearing T cells in vivo.[372,373] The signaling moiety of CARs has evolved from CD3 ζ alone, which was insufficient to drive cytokine production and T cell expansion, to dual or multiple signaling modules. Including the cytoplasmic domain of CD28, 4-1BB, OX40, or others significantly enhanced the activity of CARs when expressed in primary T cells.[365] CARs directed against CD19 have had recent success in the treatment of human B cell malignancies, including chronic lymphocytic leukemia and acute lymphoblastic leukemia,[374-376] and a host of other malignancies are being targeted with this novel technology.

PERIPHERAL T-CELL MATURATION

A hallmark of adaptive immunity is the generation of an antigen-specific response that can be rapidly recalled upon reexposure to the same antigen at a later time.[377,378] Naïve T cells released from the thymus have a broad range of TCR specificities, with few clones that recognize any given antigen, and they generally do not proliferate in the absence of cognate antigen. Exposure to antigen results in differentiation and rapid proliferation of the specific naïve precursor population into effector T cells that either kill targets bearing cognate antigen in the case of CD8+ T cells or produce polarized sets of effector cytokines in the case of CD4+ T cells. The expansion of effector cells is rapid and brief, with the majority dying by activation-induced cell death. Long-lived memory T cells that survive after the effector response serve to increase the precursor frequency in the periphery and thus arm the organism for a more rapid and efficient response on subsequent exposure to the same antigen.

Naïve T-Cell Differentiation to Effector and Memory T Cells

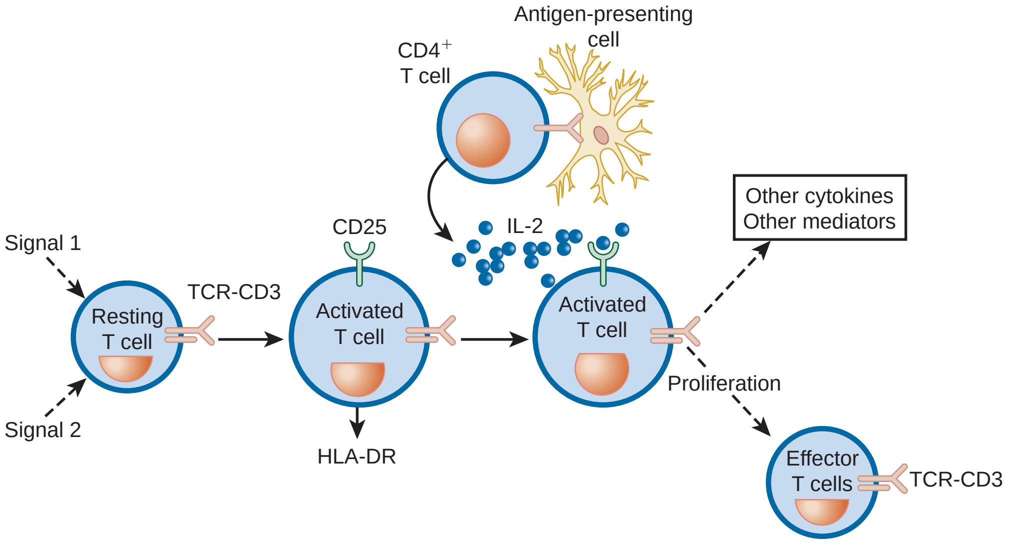
Circulating naïve, effector (activated), and memory T cells can be differentiated by phenotypic differences as well as by genetic changes (Fig. 23-16). With T-cell activation, a number of cell surface receptors, including CD2, CD58, LFA-1, CD29, and CD44, are upregulated and increase the avidity of the interaction between the T cell and the antigen-bearing APC. CD45RA, which is constitutively expressed on naïve T cells, is downregulated and replaced by the CD45RO isoform.[379]

More recently, human T-cell memory populations have been further characterized by the expression of CD62L (L-selectin) and the chemokine receptor CCR7 as either effector memory (CCR7–) or central memory (CCR7+) subsets. CCR7 is a lymph node–homing receptor that interacts with its ligand SLC on endothelial cells.[380] It is proposed that differential CCR7 expression serves to segregate effector memory cells to tissues, where they rapidly release cytokines and kill targets, and central memory cells to lymph nodes, where interactions with dendritic cells and B cells orchestrate effective T-cell help and secondary proliferation.[381,382] In addition to these cell surface markers, tetramer-based technology now allows identification of antigen-specific CD8+ memory cells on a research basis.[383] Four class I MHC molecules are bound covalently and tagged with fluorescent marker and then loaded with specific cognate peptide.[384] T cells that recognize that MHC-peptide complex bind the tetramer and can be identified by flow cytometry.

Helper T-Cell Differentiation and Function

CD4+ helper T cells are now known to further differentiate into distinct subsets with specialized functions. The cytokines elaborated during the normal innate inflammatory response to pathogens results in induction of master transcription factors that drive differentiation into the appropriate pathway, thereby tailoring the immune response to the pathogen in question. Currently 5 T_H subtypes have been identified: T_H1, T_H2, T_H17, inducible Treg (discussed later), and T_{FH}. Although these subsets are frequently referred to as *lineages,* the growing evidence of plasticity between these cells, most notably the conversion of T_H17 cells into iTreg, strengthens the argument that they should be classified as subsets rather than lineages.[207]

Effector helper T cells were first described to differentiate from naïve CD4+ T-helper precursors (T_Hp) into two main classes of T_H cells with distinct functional properties.[385,386] A panoply of factors in the microenvironment where antigen recognition occurs have been shown to influence the differentiation of T_H cells, including the nature and density of ligand, the strength of TCR ligation, the presence and kinds of costimulatory molecules, and the differentiation state of the APC.[387] The cytokines in the immediate milieu are thought to be critical and result in vitro and in vivo in the early upregulation of canonic transcription factors that drive the T_H cell to one subset while suppressing the transcriptional program characteristic of other subsets (Fig. 23-17).[388,389] For instance, under the influence of IL-12 and IFN-γ, the transcription factor T-bet is upregulated and drives the cell to the so-called T-helper type 1 (T_H1) subset, which is characterized by production of the inflammatory cytokines IL-2, IFN-γ, and TNF-α.[390] These cytokines drive



Changes in receptor function

Resting T cells	Qualitative	Quantitative	Memory T cells
CD45RA$^+$	CD8	HLA-DR	CD45RO$^+$
CD29^{low}	LFA-1	CD71	CD29^{high}
CD2^{low}	CD2	CD25	CD2^{high}
CD58^{low}	VLA-4	CD26	CD58^{high}
LFA-1^{low}			LFA-1^{high}
CCR7^{high}			CD44^{high}
CD62L^{high}			CD62L^{low}
			CCR7^{high} (central memory)
			CCR7^{low} (effector memory)

Figure 23-16 T-cell activation resulting in proliferation, acquisition of immunocompetence, and memory. Resting T cells are stimulated by antigen/major histocompatibility complex (MHC) molecules in the presence of a number of secondary signals. Appropriate activation results in an increase in both cell size and entry into the cell cycle. The high-affinity interleukin-2 (IL-2) receptor is expressed on the cell surface. Other activation antigens, such as transferrin receptor (CD71) and HLA-DR, are also expressed on the cell surface. The T cell is stimulated to produce cytokines (e.g., IL-2) that act in an autocrine and paracrine fashion on the T cell to promote cell replication and maturation to effector cells. CD4+ T cells generally differentiate to become helper T cells that are able to secrete IL-2 and other cytokines in response to peptide antigen in the context of MHC class II proteins. These cytokines in turn help B cells and other T cells to proliferate and differentiate. T lymphocytes that express CD8 on their cell surface generally function as cytotoxic T lymphocytes (CTLs) and are able to kill target cells that express a foreign peptide antigen or viral product in the context of MHC class I proteins. In addition, a certain proportion of CD8+ T cells function as suppressor T cells and inhibit the ability of B cells to secrete immunoglobulin, the generation of CTLs, or the production of cytokines by CD4+ cells. A small proportion of circulating, stimulated T cells become immunocompetent memory T cells that are able to respond to antigen exposure in a secondary immune response. The phenotype of resting T cells changes upon T-cell activation, transcriptional activation, and acquisition of the memory phenotype. Certain cell surface receptors are upregulated quantitatively as shown, within days after activation. Although the level of expression of the TCR complex remains constant, that of CD2, CD58, CD29, and CD44 increases. L-selectin expression decreases, and CD45RA expression falls. Expression of CD45RO is characteristic of the memory phenotype. In addition to early (e.g., CD2) and late (e.g., VLA-1) quantitative changes in receptor expression, the avidity of a number of T-cell surface receptors is changed quantitatively after T-cell triggering. The avidity of LFA-1 (CD11a/CD18) for its ligands is upregulated after T-cell stimulation, as is CD8 for MHC class I proteins, CD2 for CD58, and VLA-β_1 receptors for their ligands. The specific and dynamic regulation of T-cell avidity may impart sensitivity and plasticity to the immune response.

paracrine expansion of T cells and activation of macrophages and other innate cells, thus providing help to CD8+ T cells and promoting cell-based immune responses. IL-4 in the environment, in contrast, upregulates the transcription factor GATA-3, thereby directing the cell to a T-helper type 2 (T_H2) cell fate.[391,392] The elaboration of T_H2 cytokines such as IL-4 promotes class switching of B cells and is important for T-cell–mediated help for humoral responses. IL-4 and other T_H2 cytokines such as IL-5 and IL-13 also promote eosinophil differentiation, IgE production, and the expulsion and control of parasites. Imbalance of T_H1 and T_H2 cell responses is thought to play a role in the development of autoimmunity, allergy, and asthma.

T_H17 cells (see Fig. 23-17) are a more recently defined subset, characterized by high-level production of the cytokine IL-17, which participates in the normal immune response to bacteria and fungi, and in pathogenic processes such as autoimmunity.[393-396] Differentiation along the T_H17 pathway is induced by exposure to TGB-β and IL-6, which upregulate the master regulator RORγt (encoded by *RORC*)[397]; the paracrine expansion

Figure 23-17 Differentiation of naïve CD4+ cells to T-helper subsets (T_H1, T_H2, T_H17, T_{reg}, T_{FH}). The mechanisms of development of these subsets have largely been delineated in murine models, and polarization of human CD4+ T cells into these subsets in general is less distinct than murine. In the case of T_{reg}, polarization of in vitro of human T-helper cells using cytokines as described in the mouse does not result in cells with strong suppressive capacity. Naïve CD4+ cells, stimulated by ligation of the T-cell receptor and costimulatory molecules, differentiate into four classes of helper T cells. T_H1 cells produce inflammatory cytokines, characterized by interferon-γ (IFN-γ) and interleukin-2 (IL-2), that are capable of activating macrophages and promoting the further expansion of T cells; they appear to be the principal effectors of cell-mediated immunity. T_H2 cells produce IL-4, IL-10, and IL-5, among others, important for IgE production by B cells and differentiation of eosinophils, and thus are the principal effectors of humoral immunity. The cytokines produced by T_H1 cells (IL-2, IFN-γ, and IL-12) inhibit the induction of T_H2 differentiation, whereas the cytokines produced by T_H2 cells (IL-4 and IL-10) reciprocally inhibit the differentiation of T_H1 cells. T_H17 and T_{reg} cells both arise out of TGF-β rich environments with IL-6 driving towards T_H17 and all-trans retinoic acid (ATRA) driving towards T_{reg}. T_H17 cells produce IL-17A, IL-17F, IL-22, and IFN-γ, which stimulate and recruit innate immune cells to function particularly at mucosal surfaces. There is plasticity between T_H17 and T_H1 cells. T_{reg} cells in the mouse induced from naïve T-helper cells by exposure to TGF-β and ATRA and in vivo–derived human T_{reg} cells expressing FOXP3 exhibit suppressive activity of conventional T cells. T_{FH} cells arise in the secondary lymphoid organs through a combination of exposure to cytokines and cell-cell contact with dendritic cells and B cells, in a two-way interaction that leads to differentiation of T helper cells into T_{FH} and naïve B cells into germinal center B cells. *TNF-α*, Tumor necrosis factor α.

of T_H17 committed cells and further maturation of effector function appears to be driven by IL-21 and IL-23.[398-401] The primary cytokine made by T_H17 cells is IL-17A, but other inflammatory cytokines are produced, including IL-17F, TNF-α, IL-22, and IL-26. T_H17 cells express a variety of chemokine receptors such as CCR6, CCR4, and CXCR3, which in turn induce trafficking of T_H17 cells to skin and mucosal surfaces; the IL-17 elaborated induces epithelial cells to produce IL-8 and other mediators of neutrophil migration; and IL-22 induces the production of antibacterial peptides such as defensins.[402] Thus in murine models T_H17 cells are critical for handling of bacterial infections at mucosal surfaces such as *Klebsiella pneumoniae*, *Streptococcus pneumoniae*, and others.[402] T_H17 cells have been increasingly implicated in a number of pathogenic inflammatory conditions in humans, including arthritis, multiple sclerosis, inflammatory bowel disease, asthma, transplant rejection, and GVHD.

T_{FH} cells are professional providers of T-cell help to B cells in the B-cell follicles of the GC, as reviewed previously. T_{FH} cells are induced to differentiate by the master regulator BCL6, which has been shown to be both necessary and sufficient in murine models.[219,220,403] These cells are primarily localized in GC; express CXCR5, SAP, and high levels of ICOS; and are high producers of IL-21, which in turn is critical for the induction of class switch recombination and differentiation of B cells into antibody-secreting cells.[209-211,213,217,404,405] Cells of a similar phenotype can be found circulating in the peripheral blood of mice and humans, although the relationship of these T_{FH}-like cells to their counterparts in the spleen or tonsil remains to be clarified.[207,212,404,405] The process of complete differentiation into T_{FH} cells is not a one-way interaction with B cells; rather, there are multiple lines of evidence that B cells, particularly antigen-specific B cells, are required.[219,406,407] This fact is underscored by human and murine models of deficiency in B-cell development that are also associated with a lack of T_{FH} cell development.[408]

Cytotoxic T-Cell Differentiation and Function

The primary function of effector CD8+ T cells is direct killing of APCs infected by virus or other intracellular organisms. Cytotoxicity is antigen dependent; is contact dependent; and does not result in destruction of the cytotoxic T cell itself, which can kill multiple targets serially. At least two mechanisms of cytolysis are now recognized: cytotoxic granules and the Fas-Fas ligand pathway. Effector CD8+ T cells release the contents of cytotoxic granules into the immune synapse after contact with an infected cell. The main components of these granules are perforin and the serine esterases granzyme A and granzyme B.[409,410] Perforin molecules form multimerized pores in the target cell and are classically thought to mediate delivery of granzymes into the cytoplasm. Targets then die by a combination of osmotic swelling and proteolytic damage. The importance of perforin in both responses to infection and immunoregulation is apparent by the study of patients with congenital mutations in both alleles of perforin, which results in congenital hemophagocytic lymphohistiocytosis.[411,412] Because perforin is also produced by NK cells (discussed later), this disease is characterized by deficiencies in both CD8 cell and NK cytotoxic function. The second mechanism is induction of caspase-mediated apoptosis by engagement of CD95 (Fas, Apo-1) on target cells with its ligand CD95L (Fas ligand, CD178) on effector CD8+ T cells. CD95L is not constitutively expressed on naïve T cells and is upregulated on activation of T cells and NK cells. That this pathway also has important immunoregulatory function is demonstrated by the fact that mutations in CD95 or CD95L typically cause not overwhelming infection but generalized lymphoproliferation and autoimmunity in humans, the autoimmune lymphoproliferative syndrome.[413,414,415]

Control of the Immune Response: Regulation and Termination of T-Cell Activation

Maintaining a state of unresponsiveness to self-antigens, or self-tolerance, is as important for a healthy immune system as recognition of nonself, or foreign, antigens from infectious agents or tumors. Failure of self-tolerance can lead to autoimmunity. The main mechanisms of tolerance include central or clonal deletion (deletion by negative selection in the thymus, discussed earlier), anergy, activation-induced cell death (AICD; termination of T-cell activation), and cell-mediated suppression or regulation.

A productive T-cell response requires stimulation by antigen-MHC complexes via the T-cell receptor (signal 1) and appropriate costimulation (signal 2). T cells that encounter antigen in the absence of costimulation enter a state of anergy. *Anergy* is generally defined as the inability to proliferate to a specific antigen when rechallenged while maintaining the ability to proliferate in response to cytokine (i.e., IL-2).[319,416] Anergy ensures that autoreactive T cells that encounter peripherally expressed antigens in a noninflamed environment, where costimulatory molecules on APCs have not been upregulated, are not activated. AICD is important to ensure that the robust clonal expansion of antigen-specific T cells is short-lived and contracted. T cells exposed to foreign antigen or autoreactive T cells that escape thymic deletion and encounter self-antigen in the periphery can be killed by the CD95-CD95L pathway, which activates caspases and other death signals. The importance of the CD95-CD95L pathway for control of lymphoproliferation in humans is demonstrated by the autoimmune lymphoproliferative syndrome (ALPS). Patients with ALPS have mutations in CD95 or more rarely CD95L or caspases, which leads to uncontrolled lymphoproliferation and autoimmunity.[415]

T cells that mediate suppression or regulation of other T cells have long been purported to exist. A subset of CD8+ T cells, so-called suppressor cells, have been described, but in recent years a distinct population of mostly CD4+ T cells with regulatory properties has emerged as an important effector of cell-based regulation. This population of T-regulatory (Treg) cells can be distinguished from other CD4+ T cells by the expression of certain cell surface receptors, most commonly CD25,[417] and more recently by expression of a key transcription factor, Foxp3.[418,419,420] Foxp3 expressing Treg can be divided into two types: those that arise continuously during development in the thymus (so-called *natural Treg*, or nTreg) or are formed during the course of an antigen-specific immune response in the periphery (so-called *inducible Treg*, or iTreg).[421,422] FoxP3+ CD4+ CD25+ T cells develop in the thymus and in murine and human models require IL-2 for development and maintenance.[423] Humans deficient in *FOXP3* have the immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, which is characterized by autoimmune diabetes and thyroiditis, inflammatory bowel disease, allergy, and other organ-specific autoimmunity.[424-426] In vitro, suppressive activity of these cells is defined by the ability to depress proliferation by lymphocytes stimulated via the TCR.[427-429] In vivo depletion of these cells in mice leads to spontaneous autoimmunity, whereas cotransfer suppresses autoimmunity in various models.[423] The iTreg can arise from Thp after exposure to TGF-β and derivatives of vitamin D. They can be distinguished from nTreg on the basis of expression of Helios, and the demethylation state of the *FOXP3* locus.[430,431] The shared requirement for TGF-β for both T_H17 and iTreg development, and the finding that interconversion of these cells can occur has led to a model featuring co-development and plasticity between these two subsets.[432,433] Likewise, perturbation of a coordinated and flexible response of T_H17 and iTreg may underlie the pathogenesis of inflammatory disease.

NONCONVENTIONAL T-CELL SUBTYPES

In addition to conventional TCR αβ–bearing T cells that recognize peptide antigens, other nonconventional smaller populations of T cells exist. The function of these cells is less well characterized, but their conservation through evolution implies nonredundant roles in the immune system. Both populations share the ability to bind to the nonclassic MHC molecules and have restricted TCR diversity. They are generally believed to have functions during the innate immune response. Additionally, a host of innate lymphoid cells have been characterized; these are beyond the scope of this chapter, but they have been reviewed recently. These innate lymphoid cells appear to have critical functions at mucosal surfaces such as lung, gut, and skin.[434-436]

Development and Function of CD1-Restricted T Cells or Invariant Natural Killer T Cells

A subset of T cells that bear αβ TCR but recognize lipid antigens rather than peptide antigens has been defined in several ways over the past couple of decades. These cells were first characterized in the mouse as TCR αβ T cells that co-expressed cell surface markers also found on NK cells such as NK1.1 (CD161) and therefore were termed NK T cells.[437] When it was found that a subset of NK T cells recognize the CD1 family of nonclassic MHC molecules,[438] the term *CD1-restricted T cells* was adopted as a more precise functional definition; conversely, not all CD1-restricted T cells express NK1.1. CD1 is a family of proteins with one isoform in the mouse, CD1d, and five isoforms in humans, CD1a, CD1b, CD1c, CD1d, CD1e, the last of which is not expressed on the cell surface.[439] These MHC class I–like proteins are generally expressed in a complex with β_2-microglobulin. The diversity of TCRα rearrangements used by CD1d-restricted T cells is limited, with many bearing Vα24-Jα18 rearranged TCRα protein, preferentially complexed to a Vβ11 TCRβ protein. Thus the term *invariant NK T cells* is also used to distinguish this main population from those with diverse αβ TCR restricted by CD1 molecules, and most studies have focused on the invariant CD1d-restricted subset.

Invariant NK T cells develop in the thymus, arise from the DP stage of development, and in murine models are selected by other DP thymocytes that express CD1d rather than by thymic stroma.[440] In contrast to conventional T cells, invariant NK T cells recognize lipid presented by CD1.[441] A number of foreign lipids and glycolipids have been identified that are recognized by invariant NK T cells, although the discovery of self-antigens has been more elusive.[442] In the laboratory, α-galactosylceramide, derived from marine sponge, is a highly potent agonist for invariant NK T cells[443] and can be loaded onto tetramers of CD1d molecules tagged to fluorescent molecules to identify human or mouse invariant NK T cells by flow cytometry, similar to MHC tetramer technology.[444,445] The structure of the human NK T-cell receptor complexed to CD1d loaded with α-galactosylceramide has been reported and yields interesting insights into the plasticity of this particular TCR.[446] In humans, about half of these cells do not express either CD4 or CD8 and half express CD4.[447] Invariant NK T cells produce cytokines, such as IL-4 and IFN-γ, more rapidly than conventional TCR αβ T cells do, within hours in mice after in vivo injection with antigen.[448] This early secretion has been proposed to function as a bridge between innate and adaptive immunity in diverse processes, including the response to infection, antitumor immunity, autoimmune disease, and asthma.[449] In sickle cell anemia, invariant NK T cells are both more numerous and hyperactivated; the adenosine A2A receptor agonist regadenoson has recently been shown to modulate invariant NK T cell number and activation state in patients with sickle cell anemia during vaso-occlusive crisis.[450,451]

DEVELOPMENT AND FUNCTION OF T-CELL RECEPTOR γδ T CELLS

TCR γδ T cells can be identified in mammals, chickens, and even cartilaginous fish, though not in jawless fish.[452] Although they develop in the thymus alongside TCR αβ T cells, in contrast to conventional T cells, the variety of γδ receptors is highly restricted, with six V_γ genes used (5 $V_\gamma1$ and 1 $V_\gamma2$) and 8 to 10 V_δ genes, three of which are commonly used in humans.[452,453] TCR γδ T cells make up a very small percentage of cells in the thymus or lymph node, on the order of 1% to 2%, but are much more abundant in mucosal surfaces, particularly the human gastrointestinal tract. Interestingly, the distribution of human TCR γδT cells is skewed toward particular γδ combinations: peripheral blood contains a preponderance of $V_\gamma9V_\delta2+$ T cells, whereas TCR γδ T cells found in intestinal epithelium often bear $V_\delta1+$ or $V_\delta3+$ TCR.[453] Most of these cells do not express either the CD4 or CD8 coreceptor. Although it is known that γδ rearrangement precedes αβ rearrangement and that γδ development occurs early during embryonic life, whether γδ development depends on ligand binding is unclear. Indeed, the natural ligands of TCR γδ T cells remain poorly defined but can be nonpeptides, as shown for circulating human TCR γδ T cells that recognize mycobacterial antigens.[454-456] $V_\gamma9V_\delta2+$ T cells can generally recognize various types of phosphoantigens, whereas non-Vδ2+ T cells have more diverse ligands, including MHC class I–like molecules such as CD1. TCR γδ T cells can be expanded during responses to a variety of infections and tumors.[453]

NATURAL KILLER CELL DEVELOPMENT AND FUNCTION

In the peripheral blood of all human beings are circulating lymphocytes that morphologically resemble large granular lymphocytes and have distinctive physical characteristics that allow enrichment on a Percoll density gradient in vitro. These cells are termed *NK cells* and consist of a distinct subset of lymphocytes that, unlike T lymphocytes, do not rearrange the T-cell antigen receptor genes (see Table 23-1).[457] These cells have the capacity to mediate the spontaneous lysis of sensitive target cells, including certain tumor cells, virus-infected cells, and hematopoietic cells, and to mediate ADCC.[458,459] NK cells appear to lyse their targets by pathways similar to those used by cytotoxic T lymphocytes.[458-460] NK cells have been shown to have a role in allograft rejection and tumor surveillance. Despite the relative homogeneity of their morphologic appearance and function, NK cells are clearly a heterogeneous population of cells. NK cells are derived from a common lymphoid precursor cell. Peripheral blood NK cells may be derived directly from precursors in the bone marrow or may transit through the thymus, although the thymus is not required for their development. Phenotypic and functional NK cells may arise from immature CD7+ CD1– TCR– CD3– CD4– CD8– prothymocyte precursors,[461,462] and they express CD2. Recent data indicate that Flt3L, IL-15, and IL-21, a cytokine closely related to IL-2 and IL-15, are all involved in NK hematopoietic development and expansion.[214] More recent evidence suggests that NK cells in humans can also mature in secondary lymphoid tissue.[463]

In addition to a role in immune surveillance, a role has been documented for NK cells in protection from viral infections, which is particularly important in the early phases of an immune response before T-cell recruitment. Indeed, NK cells are critical for protection against latent DNA viruses of the herpes family inasmuch as individuals with a deficiency in NK cell number or function typically have overwhelming herpesvirus infections.[460] Viral infection can trigger NK cell activity in several ways. First, elaboration of cytokines such as IFN-α, IFN-β, and IL-12 by infected cells, particularly monocytes, macrophages, and dendritic cells, induces NK cells to produce IFN-γ.[464] Second, cells expressing viral antigens that are then coated with specific Ig can bind to FcR on the surface of NK cells and trigger ADCC. Finally, NK cell surface receptors that usually recognize MHC class I and class I–like molecules mediate so-called *missing self-recognition*.

NK cells interact with and are regulated by nonclassic MHC class I molecules. The killer cell Ig-like receptors (KIRs) recognize HLA class Ia and class Ib proteins, including HLA-G.[465] Members of a related family, termed *Ig-like transcripts* or *leukocyte Ig-like receptors (LIRs)*, also recognize HLA class I proteins and are expressed not only by NK cells but also by cells of the myelomonocytic lineage.[466] These families of receptors act as inhibitory receptors that downregulate NK cell activity on recognition of ligand by recruiting negative regulatory signaling proteins (e.g., tyrosine phosphatases) to the receptor complex.[467,468] Thus NK cells can be activated or inhibited by HLA class I–like molecules; net activity depends on expression of these receptors and expression of MHC class I molecules on the target cells. Viruses may use the ability to downregulate MHC class I expression as a means of subverting the immune response; cells with low class I MHC expression are, however, targets of NK cytotoxicity. Significantly, human cytomegalovirus expresses an MHC class I homologue, UL18, which associates with β_2-microglobulin and endogenous host peptides. UL18 binds with high affinity to LIR-1 and related NK molecules, thereby effectively competing with host class I molecules, and escapes immune recognition.[469-471]

CONCLUSIONS

T and B cells play a central role in the acquired immune response, and NK cells are an early and critical effector of the innate immune response. The evolution of an adaptive immune response with the capacity for long-lived anamnestic responses affords exquisite specificity and adaptability to higher animals such that novel infections or arising malignancy can be both cleared initially and protected against upon reexposure. Indeed, the requirement for T-cell function in normal homeostasis is exemplified by the consequences of its suppression. Deficiency of T-cell function associated with acquired immunodeficiency syndrome (AIDS), allogeneic stem cell transplantation, or T-cell–directed immunosuppressive therapy places patients at risk for herpes family viral reactivation (herpes simplex, herpes zoster, and cytomegalovirus) and lymphoproliferation (particularly Epstein-Barr virus–transformed B-cell lymphomas). As the mechanisms of immune control of nascent malignant degeneration become better understood, strategies to improve control of cancer by immunomodulatory therapy may become more tractable.

The same acquired immune response that gives higher animals an advantage in control of infection conversely predisposes these same species to the unique problems of autoimmunity. Failure of self-tolerance may result from the dysregulation of host T-cell responses after exposure to specific antigens in the setting of specific MHC molecules. Self-reactive B-cell clones may also mediate autoimmunity through inappropriate production of self-antigen–specific antibodies directed against a variety of tissue-specific targets. That enhancement of immune responses can precipitate autoimmunity is exemplified by the development of autoimmunity in melanoma patients who experienced tumor regression after peptide vaccination in the context of immunostimulatory anti–CTLA-4 antibody.[472,473] Greater understanding of antigen-specific activation and tolerance should open the way to the development of targeted immunomodulation and carry the field beyond global suppression of T-cell responses.

These authors had previously identified a cell surface protein that is the ligand on T cells for CD40 on B cells, then demonstrated that three boys with a severe defect in class-switching of B cells had mutations in the gene for CD40 ligand on the X chromosome.

366. Eshhar Z, Waks T, Gross G, et al: Specific activation and targeting of cytotoxic lymphocytes through chimeric single chains consisting of antibody-binding domains and the gamma or zeta subunits of the immunoglobulin and T-cell receptors. *Proc Natl Acad Sci U S A* 90:720–724, 1993.

These authors were the first engineers of so-called first-generation chimeric antigen receptors (CARs), expressing a fusion molecule containing the specificity determining regions of an immunoglobulin molecule to T-cell signaling machinery.

377. Kaech SM, Cui W: Transcriptional control of effector and memory CD8+ T cell differentiation. *Nat Rev Immunol* 12:749–761, 2012.

This recent review summarizes the wealth of literature regarding the transcription factors that control CD8 T-cell effector expansion, contraction, and establishment of memory.

382. Sallusto F, Lenig D, Förster R, et al: Two subsets of memory T lymphocytes with distinct homing potentials and effector functions. *Nature* 401:708–712, 1999.

Non-naïve human CD4 and CD8 T cells were found by these authors to have different patterns of expression of the chemokine receptor CCR7, which distinguish effector memory cells with rapid effector function and central memory cells that provide optimal stimulation to APCs in the secondary lymphoid organs. The specialized characteristics of these two circulating memory subsets in turn can be exploited to define the optimal subsets to subject to T-cell engineering of responses against tumors.

385. Mosmann T, Coffman R: TH1 and TH2 cells: different patterns of lymphokine secretion lead to different functional properties. *Annu Rev Immunol* 7:145–173, 1989.

These authors established the paradigm of distinct subsets of helper T cells that are induced to produce different cytokines based on the cytokine milieu in which that T cell encounters antigen. This paradigm continues to be important today and additional subsets of Th cells have been identified that produce IL-17, regulate other immune cells, or provide professional B cell help.

390. Szabo SJ, Kim ST, Costa GL, et al: A novel transcription factor, T-bet, directs Th1 lineage commitment. *Cell* 100:655–669, 2000.

This paper reported the discovery of a novel transcription factor that is the master regulator for Th1 cell development.

401. Bettelli E, Carrier Y, Gao W, et al: Reciprocal developmental pathways for the generation of pathogenic effector TH17 and regulatory T cells. *Nature* 441:235–238, 2006.

At a time when the cytokines responsible for driving IL-17 producing T helper cells (Th17) were just being elucidated, these authors demonstrated that T helper cells exposed to TGF-β could be driven into the inflammatory Th17 rather than the regulatory T cell lineage with the addition of IL-6.

410. Podack ER, Konigsberg PJ: Cytolytic T cell granules. Isolation, structural, biochemical, and functional characterization. *J Exp Med* 160:695–710, 1984.

These authors were the original describers of the contents and function of cytolytic T cell granules.

414. Rieux-Laucat F, Le Deist F, Hivroz C, et al: Mutations in Fas associated with human lymphoproliferative syndrome and autoimmunity. *Science* 268:1347–1349, 1995.

Years after the role of Fas in cell death was known, mutations in Fas were found to be the cause of autoimmune lymphoproliferative syndrome (ALPS) in three children; lack of apoptosis led not only to proliferation but also to dysregulation and autoimmunity.

419. Hori S, Nomura T, Sakaguchi S: Control of regulatory T cell development by the transcription factor Foxp3. *Science* 299:1057–1061, 2003.

A seminal article in which the authors demonstrated that the transcription factor Foxp3 is both necessary and sufficient for the development of regulatory T cells.

434. Koyasu S, Moro K: Role of innate lymphocytes in infection and inflammation. *Front Immunol* 3:101, 2012.

A review of various innate lymphocytes and their importance in inflammatory signatures and infection.

439. Brigl M, Brenner M: CD1: antigen presentation and T cell function. *Annu Rev Immunol* 22:817–890, 2004.

A summary of the development, function, and significance of NK T cells, which bear invariant or a restricted set of variant T-cell receptors restricted not by MHC class I or II but rather by CD1 molecules bearing lipid antigens.

452. Hayday A: γδ Cells: a right time and a right place for a conserved third way of protection. *Annu Rev Immunol* 18:975–1026, 2000.

A review of the function of this subset of T cells that occupies the crossroads between innate and adaptive immunity.

458. Henkart P: Lymphocyte-mediated cytotoxicity: two pathways and multiple effector molecules. *Immunity* 1:343–346, 1994.

A description of the pathways of molecules mediating cytotoxic function by lymphocytes.

476. Monks CR, Freiberg BA, Kupfer H, et al: Three-dimensional segregation of supramolecular activation clusters in T cells. *Nature* 395:82–86, 1998.

The first immunofluorescence microscopy analysis of immunologic synapse formation, including molecules involved.

    Previous to this paper, CTLA-4 was purported to have a positive regulatory role, similar to CD28, as both bind the same ligand, B7. The authors demonstrated here that deficiency for CTLA-4 led to a dramatic severe fatal aggressive lymphoproliferation, establishing that CTLA-4 has instead of a negative regulatory role. CTLA-4 blockade is now being used to enhance T cell responses against tumors.

  - Susceptibility to Trypanosomiasis
- HUMORAL IMMUNODEFICIENCY
  - The Agammaglobulinemias
  - Other Predominantly Antibody Deficiency Syndromes
  - Management of Humoral Immunodeficiency
- COMPLEMENT DEFICIENCIES
  - Deficiency of Classical Complement Pathway Components
  - Deficiency of Alternative Complement Pathway Components
  - Deficiency of Lectin Pathway Complement Components
  - Deficiency of Terminal Complement Components
  - Deficiency of Complement Regulatory Factors
  - Diagnosis and Management of Complement Disorders

Immune compromise arises either as a heritable genetic defect (primary immune deficiency diseases, PIDDs) or as a consequence of another pathologic process such as infection, malignancy, malnourishment, or iatrogenic immunosuppression (secondary immune deficiencies). Immune dysfunction in patients with PIDDs is most often manifested as recurrent and chronic infections; however, malignancy and autoimmunity are common and may be prominent in some disorders. In many cases, symptoms and signs of immunodeficiency develop soon after birth or early in childhood. However, in some forms of PIDD clinical onset may be delayed into late childhood, adolescence, or adulthood. Even though many patients with severe immunodeficiency suffer dramatic morbidity and mortality in infancy and early childhood, the majority of patients with immunodeficiency have milder forms that permit survival into adulthood, but often with reduced longevity because of infection, autoimmune disease, malignancy, or constitutional debility. Health-related quality of life is significantly impaired in individuals with PIDDs.[1,2]

PIDDs may be classified with respect to the specific immune effector mechanisms disrupted.[3,4] In broadest terms, one may distinguish: (a) disorders that affect both cellular and humoral components of specific immunity (combined immunodeficiencies); (b) defects of antibody production (antibody deficiency syndromes): (c) disorders of innate immunity (phagocytic cell defects, disorders of Toll-like receptor (TLR) signaling, complement deficiencies). Moreover, some forms of PIDD are characterized by prominent immune dysregulation. Finally, in some cases impairment of immune function is part of a broader spectrum of symptoms (syndromic immunodeficiency). Discussed here are a broad range of PIDDs arising from aberrant development and function of T and B cells, disorders with immune dysregulation, immunodeficiency syndromes, and complement deficiencies. Phagocytic disorders are the subject of Chapter 22. Table 24-1 lists several Internet sites with information relevant to primary immunodeficiencies.

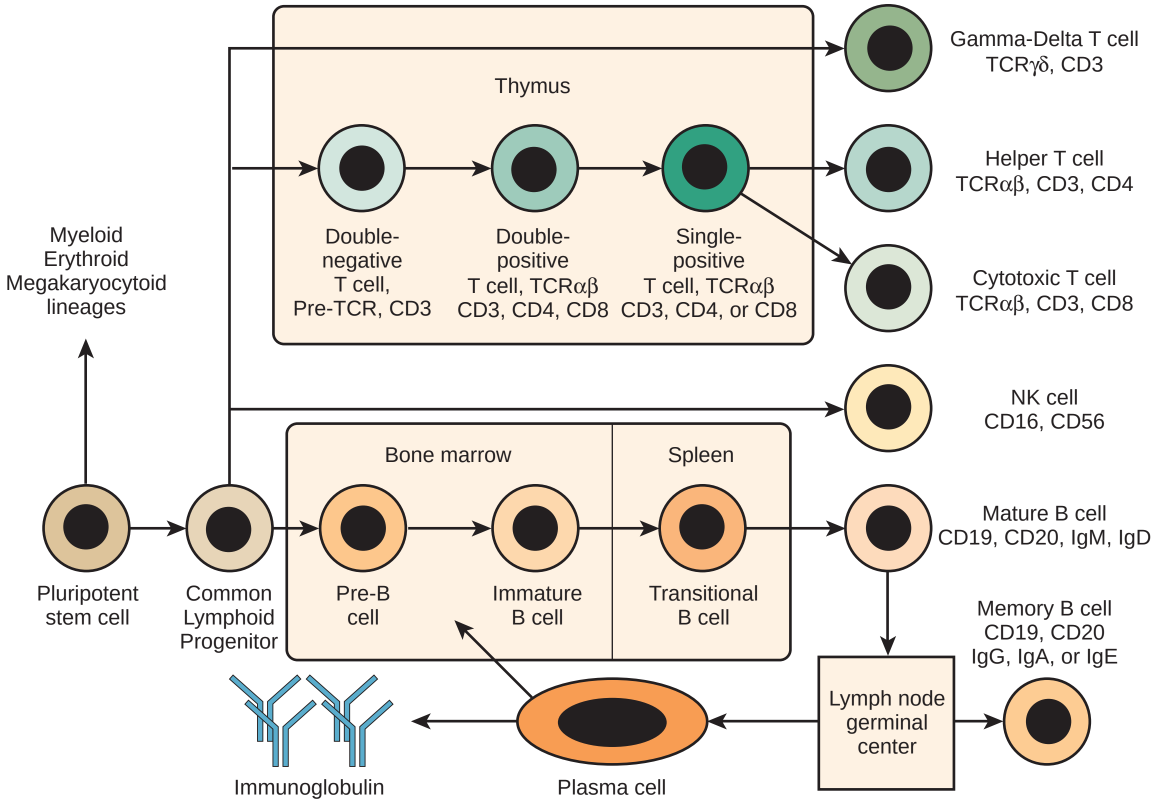
COMBINED IMMUNODEFICIENCIES

Severe Combined Immunodeficiency

The term *severe combined immunodeficiency* (SCID) designates a genetically heterogeneous group of PIDDs characterized by impaired development and function of T lymphocytes. In some cases, development of B or natural killer (NK) lymphocytes (or both) is also affected (Fig. 24-1).[3,5] However, because T cells play a critical role also in most B-cell responses, serious T-cell dysfunction precludes effective humoral immunity even in patients in whom the genetic defect does not affect B-cell development. Complete absence of specific cellular and humoral immunity in patients with SCID leads to an extreme infectious diathesis early in life. Mucocutaneous candidiasis is a common finding. Infections with common viral pathogens (e.g., varicella, herpes simplex, measles, adenoviruses, respiratory syncytial virus, influenza, and parainfluenza) are often fatal. Patients are also susceptible to opportunistic infections with commensal organisms that are normally nonpathogenic, such as *Pneumocystis jiroveci*. Even attenuated vaccine organisms such as oral polio vaccine virus, rotavirus vaccine, varicella vaccine, and bacille Calmette-Guérin (BCG) can cause severe or fatal infection. Transfusion of blood products containing viable lymphocytes may lead to fatal graft-versus-host disease. Autoimmunity and other manifestations of immune dysregulation (e.g., skin rash) are frequently observed, especially in patients with residual development of T lymphocytes ("leaky" SCID). Patients with SCID are also at increased risk of malignancies, including lymphoproliferative disorders caused by Epstein-Barr virus (EBV) and other tumors.

Typical symptoms of SCID are recurrent severe infections, chronic diarrhea, and failure to thrive.[4,5] Symptoms are often seen in the first weeks of life but may be delayed by several months. Antibodies derived from the mother by transfer across the placenta may provide some early protection. Physical examination may reveal foci of infection (e.g., thrush) and the absence of discernible lymphoid tissue. Hypogammaglobulinemia is often present but is not universal. Specific antibody responses are almost always severely impaired.

SCID is most often classified according to the peripheral blood lymphocyte phenotype—that is, absence or presence of the major lymphocyte types. T cells are absent (or very low) and nonfunctional in all classic forms of



Thymus
Gamma-Delta T cell
TCRγδ, CD3
Helper T cell
TCRαβ, CD3, CD4
Cytotoxic T cell
TCRαβ, CD3, CD8
Double-negative T cell, Pre-TCR, CD3
Double-positive T cell, TCRαβ CD3, CD4, CD8
Single-positive T cell, TCRαβ CD3, CD4, or CD8
Myeloid
Erythroid
Megakaryocytoid
lineages
NK cell
CD16, CD56
Bone marrow
Spleen
Mature B cell
CD19, CD20, IgM, IgD
Pluripotent stem cell
Common Lymphoid Progenitor
Pre-B cell
Immature B cell
Transitional B cell
Memory B cell
CD19, CD20
IgG, IgA, or IgE
Lymph node germinal center
Immunoglobulin
Plasma cell

Figure 24-1 Diagram of lymphocyte development. Pluripotent stem cells give rise to all cellular blood elements. The common lymphoid progenitor gives rise to the three principal lineages of lymphocytes: T cells, B cells, and natural killer *(NK)* cells. Most peripheral T cells express the αβ form of the T-cell antigen receptor *(TCR)* and develop through distinct stages in the thymus. Mature helper T cells express the CD3 antigen coreceptor complex along with the major histocompatibility complex (MHC) class II receptor CD4, whereas cytotoxic cells express the MHC class I receptor CD8. A minority (1% to 5%) of peripheral T cells express the γδ form of the TCR along with CD3, but without CD4 or CD8; less is known about their development. B cells develop initially in the bone marrow and pass through several stages before exiting to complete development in the spleen. Mature B cells express distinct markers (CD19 and CD20) along with surface immunoglobulin M (IgM) and IgD. B cells are activated in germinal centers to undergo class switching and become either memory B cells expressing IgG, IgA, or IgE or Ig-secreting plasma cells. Most IgG-producing plasma cells reside in the bone marrow. NK cells are a distinct lineage of cytotoxic cells; little is known regarding their development from lymphoid precursors.

SCID, a phenotype designated “T$^-$.” The presence or absence of B cells is indicated by adding “B$^+$” or “B$^-$,” respectively. The same pattern applies for NK cells. Table 24-2 lists the various lymphocyte phenotypes of SCID and the molecular defects associated with them. In as many as 40% of patients with SCID, maternal T cells may have engrafted in the fetus during gestation, and this situation may occasionally confuse the diagnostic picture.[6,7] Maternally derived T cells tend to be anergic, but they may also be associated with clinical manifestations similar to those of graft-versus-host disease, such as eczematous rash, eosinophilia, and splenomegaly.[6,7] In rare circumstances, maternal engraftment may lead to even more unusual clinical findings, such as IgA monoclonal gammopathy, autoimmune cytopenias, and allograft rejection.[7,8]

T$^-$ B$^-$ NK$^-$ Severe Combined Immunodeficiency

Adenosine Deaminase and Purine Nucleoside Phosphorylase Deficiencies. Figure 24-2 shows the salvage pathway of purine nucleotide synthesis. Deficiencies of the enzymes adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) are associated with immunodeficiency.[9,10] ADA deficiency accounts for approximately 10% to 15% of all patients with SCID, or approximately a third of SCID cases with autosomal recessive inheritance. PNP deficiency is quite rare, with approximately 70 cases reported.[11] Although PNP deficiency is mainly expressed as a somewhat selective defect in cellular immunity, it is

TABLE 24-2 Lymphocyte Phenotype Classification of Severe Combined Immunodeficiency and Associated Gene Defects

Lymphocyte Phenotype	Genes

[*] B-cell development is variably affected in nucleoside phosphorylase (NP) deficiency.

[†] *CD3G* mutations are rarely associated with a severe T-cell deficiency.

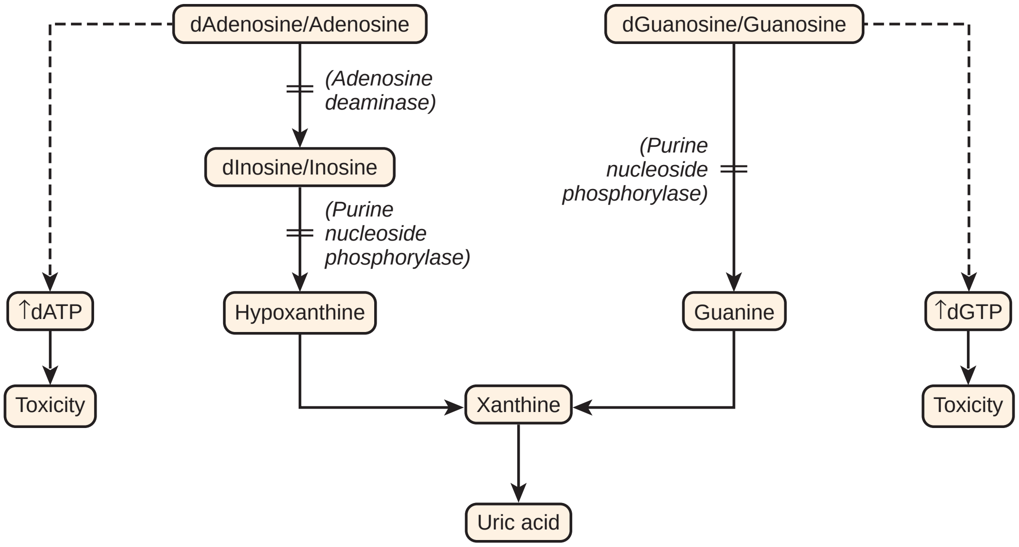

Figure 24-2 Salvage pathway of purine nucleotide biosynthesis. *d,* Deoxy; *dATP,* deoxyadenosine triphosphatase; *dGTP,* deoxyguanosine triphosphatase.

discussed here because of similarities in their biochemical pathophysiology with ADA deficiency. The absence of ADA or PNP leads to intracellular accumulation of deoxyadenosine and deoxyguanosine, respectively. These molecules are not themselves toxic to lymphocytes. However, when they are converted to their 5′-triphosphates (dATP and dGTP), they inhibit ribonucleotide reductase and prevent de novo synthesis of deoxynucleotides. Without building blocks for the replication and repair of DNA, the cells cease to divide. Lymphocytes die to a much greater extent than other cell types do. In both ADA and PNP deficiency, T-cell precursors in the thymus appear to be especially sensitive to death by apoptosis (programmed cell death).[12] B cells are more often depleted in ADA deficiency than in PNP deficiency. In the latter the B-cell phenotype is more variable.

Approximately 85% of individuals with ADA deficiency will display a SCID phenotype with markedly reduced numbers of both T and B cells and low serum antibody levels. NK cells are only rarely found in patients with ADA deficiency. Additional clinical manifestations may include radiographic alterations of the ribs, vertebral bodies, and iliac crests[9] as well as sensorineural deafness,[13] liver dysfunction,[14] lung disease resembling alveolar proteinosis,[15] and cognitive impairment and other neurologic abnormalities.[16,17] Immune dysregulation is common in patients with ADA deficiency[18]; it may manifest with allergy (eczema, asthma) and autoimmunity (cytopenias, hypothyroidism, diabetes) and is associated with loss of regulatory T-cell function.[19] Rarely, ADA deficiency may present with generalized erythroderma and infiltration of skin by activated autologous T cells, resembling Omenn syndrome (OS).[20] Bone marrow hypocellularity is frequently observed in ADA deficiency; myelodysplasia also has been reported.[21] Finally, patients with ADA deficiency are at increased risk for multicentric dermatofibrosarcoma protuberans, a very rare tumor with a characteristic chromosomal translocation (t[17;22][q22;q13]) resulting in the *COL1A1*-platelet-derived growth factor β *(PDGFB)* fusion gene.[22] Between 10% and 15% of patients with ADA deficiency may have a delayed or late-onset form that may be manifested in late infancy or early childhood. These patients initially may have variable numbers of circulating lymphocytes and some humoral immunity that quickly wanes. The severity of the phenotype appears to correlate to some degree with the amount of residual ADA activity.[23] Autoimmunity is particularly common in patients with residual ADA enzymatic activity.[24]

Patients with PNP deficiency are very susceptible to viral and fungal infections. They have decreased numbers of circulating T cells, often initially with normal numbers of B cells and normal serum immunoglobulin (Ig) levels. With time, humoral immunity usually deteriorates. Approximately 50% of children with PNP deficiency have neurologic complications such as spasticity, diplegia, paresis, and other motor disorders, as well as cognitive impairment.[25] Autoimmune manifestations, especially cytopenias, are also very common.[26]

After clinical suspicion is aroused, diagnosis of ADA or PNP deficiency is not difficult. Both ADA and PNP activity is readily measurable in red blood cell or leukocyte lysates. In symptomatic patients, activity is usually 1% or less of that in normal subjects. These methods may be applied also for prenatal diagnosis on cultured amniotic or chorionic villus cells or on fetal blood sampling. PNP is required for the production of hypoxanthine, a precursor of uric acid (see Fig. 24-2). Thus individuals with PNP deficiency will have reduced serum and urine urate levels.

Several therapeutic options are available to patients with ADA deficiency, including hematopoietic stem cell transplantation (HSCT), enzyme replacement therapy (ERT) and gene therapy. Excellent results (survival >85%) have been reported after HSCT from matched sibling donors, but results of HSCT from haploidentical or unrelated donors are much less satisfactory (43% and 66% survival, respectively).[27] Moreover, patients with ADA deficiency surviving after HSCT remain at high risk of neurologic complications.[28] ERT with weekly intramuscular injections of polyethylene glycol–conjugated bovine ADA (PEG-ADA) is usually well tolerated and is effective to normalize levels of toxic phosphorylated (deoxy)adenosine derivatives and to improve immune function.[29] However, immune reconstitution is often incomplete.[30] Encouraging results have been obtained with gene therapy, associated with nonmyeloablative cytoreduction.[31,32] This represents a very important option for patients who lack a human leukocyte antigen (HLA)-identical related donor. HSCT is the only curative therapeutic option for patients with PNP deficiency.

Reticular Dysgenesis Caused by Adenylate Kinase 2 Deficiency. Reticular dysgenesis caused by adenylate kinase 2 (AK2) deficiency is a very rare autosomal recessive form of SCID, associated with agranulocytosis (with a block at the promyelocyte stage of differentiation in the bone marrow) and sensorineural deafness.[33] AK2 regulates levels of ADP in mitochondria. Deficiency of this enzyme is associated with abnormalities of energy metabolism in granulocytes and lymphocytes (especially T cells), resulting in apoptosis.[34,35] The number of circulating B and NK lymphocytes can be variably affected, and NK cell differentiation is usually preserved. Therefore, these patients most often exhibit a phenotype other than T- B- NK- SCID; however, we describe this disorder here because it also affects purine metabolism, similar to ADA and PNP deficiencies. OS with oligoclonal expansion of T cells has been described in a patient with *AK2* hypomorphic (partially functional) mutations.[36] Patients are at increased risk of myelodysplasia.[37] Sensorineural deafness reflects a role of AK2 in the stria vascularis of the inner ear.[34] Treatment is based on HSCT, but results are less satisfactory than in other forms of SCID, and use of myeloablative conditioning is required for engraftment.[38]

T$^-$B$^-$NK$^+$ Severe Combined Immunodeficiency

Defects of Recombinase-Activating Genes (RAG) 1 and 2. *RAG1* and *RAG2* encode for DNA-binding proteins that bind to specific recognition sequences flanking coding gene elements of the Ig and T cell receptor (TCR) loci. RAG1 and RAG2 initiate the VDJ recombination process by inducing DNA double-strand breaks at these loci. Proteins of the nonhomologous end-joining (NHEJ) complex ultimately join coding Ig and TCR elements, allowing expression of Ig and TCR molecules (Fig. 24-3).[39] In patients with RAG defects, B- and T-cell differentiation is arrested at an early stage of development. Therefore patients with functionally null mutations of the

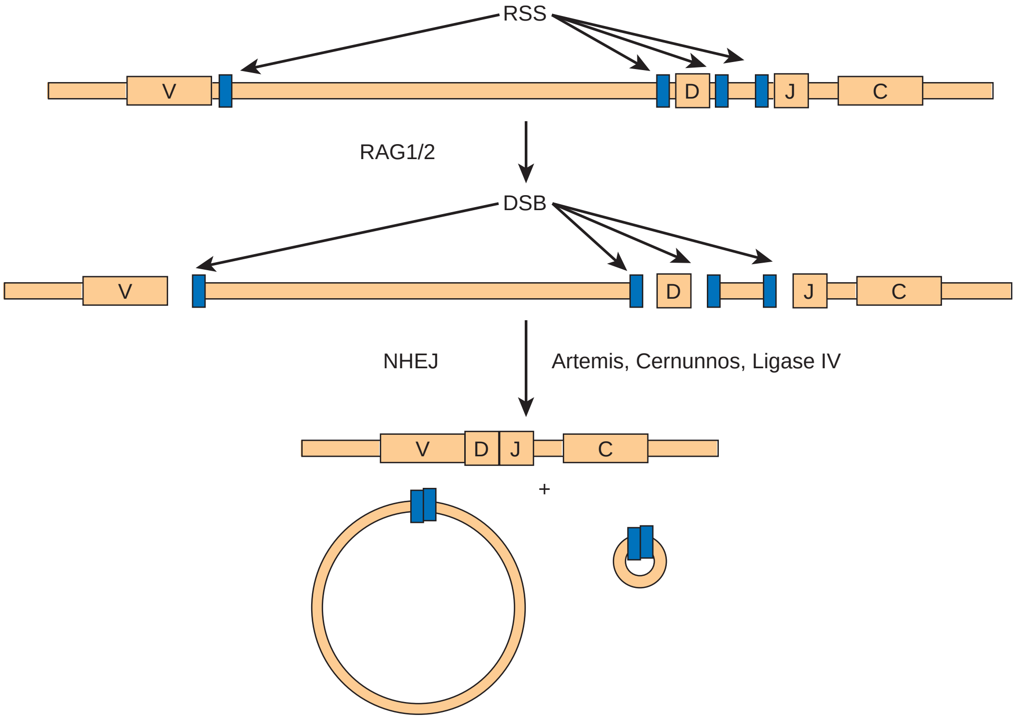

Figure 24-3 Gene defects affecting lymphocyte antigen receptor gene rearrangement and causing T$^-$B$^-$NK$^+$ severe combined immunodeficiency. The genes that encode immunoglobulin and T-cell antigen receptors are assembled from subunit segments that are separated in the germline and undergo assembly or somatic rearrangement during lymphocyte development. In the figure, a TCR or Ig heavy-chain locus is shown. The heavy chains are composed of four distinct segments: *V,* variable; *D,* diversity; *J,* joining; and *C,* constant. Some of the segments are flanked by recombination signal sequences *(RSS)*. RAG1 and RAG2 initiate the process that leads to double-strand breaks *(DSB)* in DNA. The DNA between coding segments is looped out and forms circles, with the coding sequences joining to one another. In the case of T cells, the larger DNA circle is referred to as a *T-cell receptor excision circle*. All these DNA joins are made by a group of molecules that together subserve the function of nonhomologous end joining *(NHEJ)*.

RAG1 and *RAG2* genes have very low numbers of T and B lymphocytes, but NK cell differentiation is preserved.[40] Some patients with hypomorphic *RAG1* or *RAG2* mutations may sustain differentiation of a limited number of T and (less frequently) B lymphocytes, a condition that is also referred to as "leaky" or "atypical" SCID.[41,42] In these patients, T lymphocytes often undergo homeostatic proliferation in the periphery and acquire an activated (CD45RO+) phenotype. Oligoclonal expansion of T lymphocytes that infiltrate target tissues causing damage is observed in patients with OS.[43] Patients with OS present with clinical features suggestive of acute graft-versus-host disease. Symptoms include recurrent severe infections, failure to thrive, chronic severe diarrhea, and erythroderma with exfoliation and exudation. Examination may reveal hepatosplenomegaly and lymphadenopathy. Laboratory studies show anemia, hypogammaglobulinemia with an elevated IgE level, a decrease in the number of peripheral B cells, and presence of activated (CD45RO+) circulating T lymphocytes with a restricted (oligoclonal) T cell repertoire. In vitro proliferation of T lymphocytes to antigens and to anti-CD3 is abrogated, whereas proliferation to phytohemagglutinin (PHA) may be variably affected.[44] Although hypomorphic *RAG1* and *RAG2* mutations are the most common form of OS, the same phenotype may be observed in patients with hypomorphic mutations in other SCID-causing genes. Some evidence suggests that expansion of oligoclonal, tissue-infiltrating T lymphocytes in patients with OS may reflect defects of T-cell tolerance. The study of thymic biopsies from patients with OS has shown abnormalities of medullary epithelial cells, with impaired expression of AIRE (autoimmune regulator, discussed later),[45] a transcription factor that promotes expression of self-antigens, thereby permitting intrathymic deletion of autoreactive T cells or their diversion to FOXP3$^+$ regulatory T (Treg) cells. Consistent with this, absence of FOXP3$^+$ cells has also been demonstrated in thymic biopsies from patients with OS.[45]

Environmental triggers may modify the disease phenotype in patients with RAG gene defects. In at least one case, progression to OS was observed in a patient with a *RAG2* mutation after infection with parainfluenza virus type 3.[46] Cytomegalovirus (CMV) infection has been associated with in vivo expansion of TCR$\gamma\delta^+$ T cells and autoimmune manifestations.[47,48] Finally, somatic mutations may become superimposed on null or "amorphic" mutations and yield mosaicism with revertant or hypomorphic populations of lymphocytes and resultant OS.[49]

Hypomorphic RAG mutations that result in production of mutated proteins with more robust (although subnormal) recombination activity have been identified in patients with delayed presentation characterized by granulomatous lesions and autoimmunity.[50,51] Occasionally, autoimmunity in patients with RAG defects is associated with preserved number of circulating B cells and normal or increased Ig serum levels. One patient with compound heterozygous missense *RAG1* mutations presented with idiopathic CD4 lymphopenia.[52]

Mutations of *DCLRE1C* (Artemis). A form of autosomal recessive SCID with the classic T$^-$B$^-$NK$^+$ phenotype has an associated feature of general radiation sensitivity not seen with *RAG1* or *RAG2* mutations and is caused by mutations in the gene *DCLRE1C* (DNA cross-link repair enzyme 1C), whose protein product is called Artemis.[53] Artemis has a critical role in the function of NHEJ, or the repair of double-stranded DNA breaks (see Fig. 24-3). During VDJ recombination, it opens the hairpins sealing the coding ends at V, D, and J elements that have been targeted by the RAG proteins.[39] Absence or impaired function of Artemis blocks T and B lymphocyte development at an early stage, similar to *RAG1* and *RAG2* mutations. Artemis is ubiquitously expressed, and loss of its function in nonhemopoietic tissues may account for nonimmunologic problems (oral and genital ulcers, dental abnormalities, and malabsorption) and for the increased cellular radiation sensitivity that these patients exhibit. OS has been observed in some patients with Artemis defects.[54] A partial form of the disease, with residual expression and function of the protein, is characterized by reduced number of circulating T and B lymphocytes and increased risk of lymphoma.[55]

DNA Ligase IV Deficiency. DNA ligase IV (LIG4) is also required for NHEJ. Mutations in the *LIG4* gene are associated with microcephaly, cognitive impairment, bone marrow failure, and cellular immunodeficiency that may manifest as T$^-$B$^-$NK$^+$ SCID, "leaky" SCID, or OS. There is profound cellular radiosensitivity. Patients are at increased risk of myelodysplasia and leukemia.[56-59]

Cernunnos Deficiency. Cernunnos (also known as XLF) is another component of the NHEJ pathway[39] and is encoded by the *NHEJ1* (nonhomologous end-joining 1) gene. Mutations of this gene cause lymphopenia, radiation sensitivity, growth retardation, microcephaly and developmental delay, bone marrow failure, and an increased risk of myelodysplasia.[60] The T-and B-cell immunodeficiency of Cernunnos deficiency is less severe than in patients with *RAG* or *LIG4* defects; however, there are quantitative and qualitative alterations of the T-cell repertoire, a severe reduction in the number of invariant NK T cells and mucosa-associated invariant T lymphocytes,[61] and abnormalities of class-switch recombination in B lymphocytes (see section on class-switch defects).[62]

DNA Protein Kinase Catalytic Subunit (DNA-PKcs) Deficiency. A homozygous missense mutation in the *PRKDC* (protein kinase, DNA-activated, catalytic polypeptide) gene, encoding for DNA-PKcs was identified in a patient with T$^-$ B$^-$NK$^+$ SCID and cellular radiosensitivity, but without microcephaly or mental retardation.[63]

T$^-$B$^+$NK$^-$ Severe Combined Immunodeficiency

X-Linked Severe Combined Immunodeficiency, Mutations of the Cytokine Receptor Common γ Chain. In Western countries, approximately 40% of all patients with SCID are males with an X-linked form of the disease, (XSCID), caused by mutations of the *IL2RG* (interleukin-2 receptor γ) gene, that encodes for the common γ chain (γ_c), shared by cytokine receptors for interleukin-2 (IL-2),

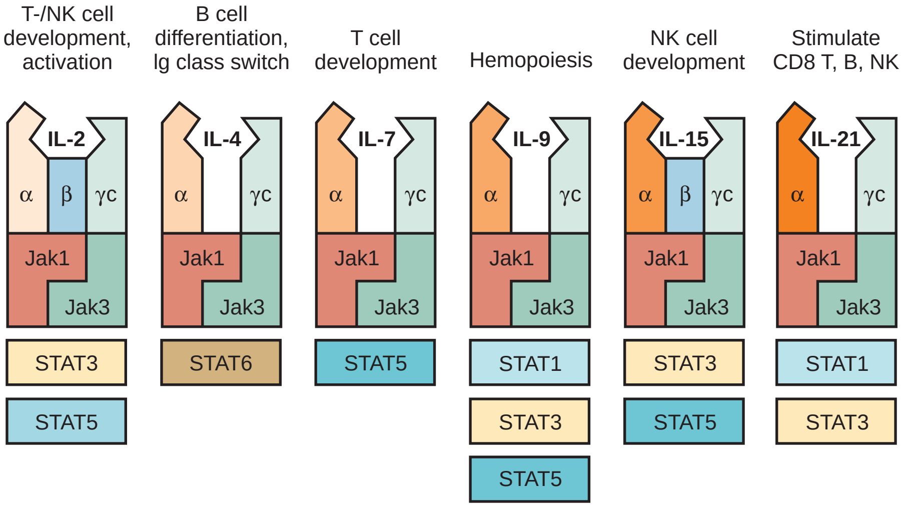

Figure 24-4 Cytokine receptors and signaling via γ_c and Jak3. The γ_c chain participates in signaling by way of all these cytokine receptors; it associates with the Jak3 kinase in every case. The α chains of each receptor are distinct; receptors for IL-2 and IL-15 also share a β chain. The α or β chains or both associate with Jak1. After cytokine binding, Jak kinases recruit STAT (signal transducer and activator of transcription) proteins. These molecules dimerize and then translocate to the nucleus, where they associate with other transcriptional regulators and alter gene expression.

IL-4, IL-7, IL-9, IL-15, and IL-21 (Fig. 24-4).[64,65] Thus a defect in a single molecule interrupts several cytokine pathways, thereby severely disrupting immune function. Typically, patients with XSCID lack T and NK lymphocytes; these defects reflect defective signaling via IL-7R and IL-15R, respectively. However, some patients with XSCID may have variable numbers of their own T or NK cells and may retain partial immune function, reflecting some preservation of γ_c expression and of cytokine-mediated signaling.[66] B lymphocytes are typically present, but they are nonfunctional as a result of impaired IL-21–mediated signaling.[67] Patients with γ_c deficiency have typical clinical features of SCID. In addition, they are unusually susceptible to chronic and severe human papillomavirus (HPV) infections, and this phenotype may not be corrected after HSCT.[68] Delayed presentations have been reported in association with hypomorphic mutations or with somatic mutations in T-cell progenitor cells, allowing generation of a diversified pool of functional T lymphocytes that may persist for years.[69-71] Gene revertant T cells undergoing in vivo expansion may also cause a phenotype resembling OS.[72]

JAK3 Deficiency. A form of $T^-B^+NK^+$ SCID phenotypically very similar to XSCID is associated with defects in the tyrosine kinase JAK3.[73] The similarity with XSCID is easily understood because JAK3 is a critical signal-transducing molecule associated with the γ_c chain (see Fig. 24-4). Hypomorphic mutations that allow residual JAK3 protein expression and function may associate with partial preservation of circulating T cells and delayed clinical onset, with lymphoproliferation and susceptibility to warts and other viral infections.[74]

$T^-B^+NK^+$ Severe Combined Immunodeficiency

Defects of the Interleukin-7 Receptor α Chain. Signaling through the IL-7 receptor (IL-7R) is required for proliferation of early T-cell progenitors and survival of T lymphocytes. The IL-7R is composed of an α chain (IL-7Rα), encoded by the *IL7R* gene, and γ_c (see Fig. 24-4). Mutations of the *IL7R* gene in humans cause $T^-B^+NK^+$ SCID.[75] One case of OS caused by a homozygous missense mutation, permissive for IL-7Rα expression, has been reported.[76]

Mutations Affecting Components of the T-Cell Antigen Receptor Complex

The TCR/CD3 complex is made up of the TCRα and TCRβ (or TCRγ and TCRδ) chains of the receptor making contact with major histocompatibility antigen-peptide complexes, as well as components of the CD3 signal-transducing complex: CD3γ, CD3δ, CD3ε, and CD3ζ (Fig. 24-5).

Defects in the CD3δ (gene *CD3D*) lead to a $T^-B^+NK^+$ SCID phenotype.[77,78] Patients have varying degrees of panhypogammaglobulinemia and are susceptible to disseminated viral infections. In some cases, a normal-sized thymus was visualized, in marked contrast to almost all other forms of SCID, in which the thymus is absent or extremely hypoplastic.[77] In one case, CD3δ deficiency was associated with OS.[79] A multicenter study of 13 patients with CD3δ deficiency treated by HSCT has shown superior immune reconstitution after transplantation from HLA-matched donors: use of conditioning chemotherapy may be needed to achieve engraftment.[79]

Deficiency of CD3ε (gene *CD3E*)[78] and of CD3ζ (gene *CD3Z*)[80,81] are associated with a similar phenotype and markedly reduced levels of the TCR/CD3 complex on the surface of circulating T lymphocytes. In one patient with CD3ζ deficiency, some of the circulating T cells were found to express normal levels of the TCR/CD3 complex as the result of somatic mutations on one of the *CD3Z* alleles, allowing expression of poorly functioning TCR/CD3 complexes.[80]

In contrast, the phenotype of CD3γ (gene *CD3G*) deficiency is heterogeneous. One of two genotypically affected siblings presented with clinical features of SCID and autoimmunity associated with severe T-cell lymphopenia, whereas the other one had a milder immunologic phenotype and remained asymptomatic until 12 years of age,

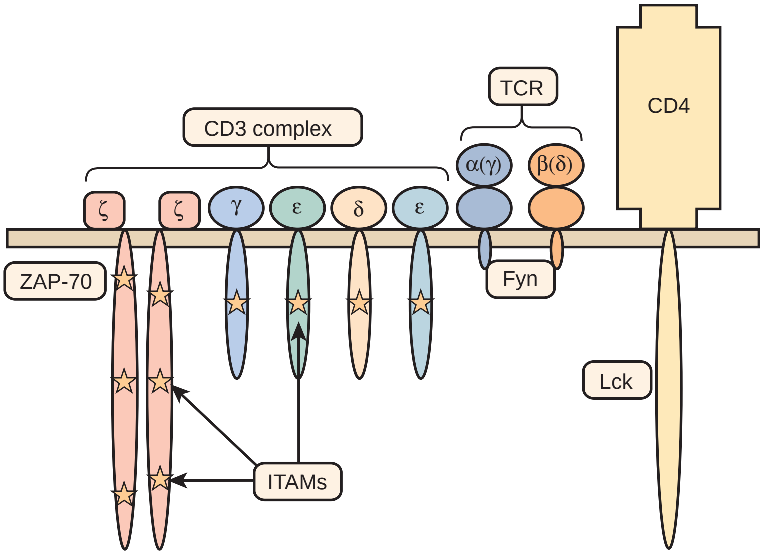

Figure 24-5 Components of the T-cell antigen receptor. The actual receptor making contact with a major histocompatibility complex (MHC)-peptide complex is a heterodimer of α and β (or γ and δ) chains. This heterodimer sits in the cell membrane in association with the signal-transducing CD3 complex. This complex contains two heterodimers, one γε and one δε, and one ζ_2 homodimer. Also shown is the MHC class II coreceptor molecule CD4. Tyrosine kinases Lck, Fyn, and ZAP-70 associate with components of the receptor complex via immunoreceptor tyrosine-based activating motifs *(ITAMs)* and transduce signals after interaction of the receptor with peptide/MHC.

when he developed autoimmunity and recurrent infections.[82,83] This variability of clinical and immunologic phenotype has been confirmed in other patients.[84]

A homozygous splice-site mutation in the TCRα constant region gene has been identified in two patients with a history of recurrent infections and autoimmunity. Development of T cells expressing TCRγδ was not affected. In vitro proliferative responses to mitogens and antigens were decreased, but specific antibody production was preserved.[85]

CD45 Deficiency

A few patients have been found to have a form of SCID resulting from mutations in the gene encoding the protein tyrosine phosphatase CD45 (gene *PTPRC*), which plays an important role in T-cell activation.[86-88] These patients have a SCID phenotype with diminished numbers of poorly functional T cells, normal or increased numbers of B cells, and variable number of NK cells.

Other Combined Immunodeficiencies (with T Cells Present)

Table 24-3 lists disorders of combined immunodeficiency with variable lymphocyte phenotypes.

Relative Deficiency of CD4+ T Cells

Lck Deficiency. The lymphocyte-specific protein tyrosine kinase (Lck) associates with CD4 and CD8 molecules and plays a critical role in T-cell signaling by mediating phosphorylation of immunoreceptor tyrosine activation motifs in the intracytoplasmic domains of CD3 subunits and of the ζ chain–associated protein of 70 kDa (ZAP70). Homozygosity for a missense *LCK* mutation was identified in a child with recurrent respiratory infections, protracted diarrhea, failure to thrive, skin nodules, vasculitis, arthritis, and autoimmune thrombocytopenia. There was a severe defect in the number of circulating CD4+ lymphocytes, and the density of both CD4 and CD8 molecules on the surface of CD3+ cells was markedly reduced. T lymphocytes showed a restricted TCR repertoire. Proliferative responses to anti-CD3 were profoundly impaired.[89]

RhoH Deficiency. The Ras homology family member H (RhoH) is a small GTPase that is phosphorylated in response to TCR stimulation, allowing recruitment of Lck and ZAP-70 to the TCR-associated signaling complex. Mutations of the *RHOH* gene have been identified in two siblings with warts, variably associated with granulomatous lung disease, psoriasiform skin changes, and molluscum contagiosum.[90] One of the affected individuals developed Burkitt lymphoma in childhood. Immunologic abnormalities included reduced number of naïve CD4+ lymphocytes and oligoclonal T cell repertoire, with accumulation of CD8+ effector memory CD45RA+ lymphocytes (TEMRA cells) with an "exhausted" (CD45RA+CCR7−) phenotype. The reduced number of lymphocytes expressing skin-homing receptors (cutaneous lymphocyte antigen, CCR4, CCR6, CCR10,

β7-integrin) may impair defense against cutaneous viral infections and contribute to development of warts.

Major Histocompatibility Complex Class II Deficiency. The major histocompatibility complex (MHC) in humans is called the HLA complex. The class I and class II HLA molecules expressed on cell surfaces are critical for practically all mechanisms of specific immune activation. Class I molecules are present on most cells of the body. They present antigenic peptides derived principally from intracellular sources to the antigen receptors of T cells expressing CD8. HLA class II molecules are generally restricted to specialized antigen-presenting cells (APCs), including monocytes and macrophages, dendritic cells, and B cells, but are also expressed by thymic epithelial cells. HLA class II molecules mainly present peptides imported from outside the cell to antigen receptors of T cells bearing CD4. Defects in the synthesis, expression, or function of HLA molecules may be expected to have profound consequences on lymphocyte development and on immune competence. In particular, defective expression of HLA class II molecules on the surface of thymic epithelial cells impairs development of CD4+ lymphocytes by impairing their positive selection.

Most patients with MHC class II deficiency present early in life with recurrent and severe infections, chronic diarrhea, and failure to thrive.[91] Chronic opportunistic infections of the gastrointestinal tract caused by *Cryptosporidium* or *CMV* organisms may lead to severe liver disease with sclerosing cholangitis. The number of circulating CD4+ cells is markedly decreased, and delayed hypersensitivity responses are impaired. All forms of MHC class II molecules (DP, DQ, and DR) are not expressed. Most patients have profound hypogammaglobulinemia; however, some patients have normal serum Ig levels, yet specific antibody responses are not elicited. As a rule, these children do not survive without HSCT. However, bone marrow transplantation in these patients has not been consistently successful,[91] probably reflecting inability to correct defective expression of MHC class II molecules on the surface of thymic epithelial cells.

MHC class II deficiency results from defective regulation of gene transcription as a result of mutations in any of four different genes *(CIITA, RFXANK, RFX5, RFXAP)* encoding for components of HLA class II transcription complex.[91] Without a complete transcription complex, no HLA class II mRNA is produced, and class II proteins cannot be synthesized. The same complex activates transcription at all HLA class II gene promoters. *RFXANK* mutations are the main cause of the disease, which is more common in Northern Africa and in the Middle East.[92]

Relative Deficiency of CD8+ T Cells

Defective Expression of HLA Class I. Several patients with defective expression of HLA class I molecules have been described.[93] These patients have mutations in one of two genes encoding either TAP1 or TAP2 (transporter associated with antigen processing 1 or 2) or in the gene encoding tapasin, a TAP-binding protein molecular chaperone. The TAP1/TAP2 heterodimer is required for shuttling of cytosolic peptides across the endoplasmic reticulum to load onto nascent HLA class I molecules for eventual expression at the cell surface and presentation to TCRs (Fig. 24-6). HLA class I molecules are highly unstable without a peptide in their binding cleft, and they are not transported to the cell surface. Patients with defective expression of HLA class I molecules suffer mainly from upper and lower respiratory tract bacterial infections, bronchiectasis, and granulomatous skin inflammation. Occasional asymptomatic individuals have also been described. The main immunologic abnormality is low peripheral blood CD8+ T cells; antibody responses may be normal.

ZAP-70 Deficiency. The ZAP-70 tyrosine kinase has a critical role in TCR-mediated signaling by inducing phosphorylation of the linker of activated T cells and SH2 domain-containing leukocyte phosphoprotein of 76 kDa (SLP-76) (see Fig. 24-5). Mutations of the *ZAP70* gene in humans are typically associated with severe, early onset infections. Patients have almost complete absence of CD8+ T cells. Although circulating CD4+ cells appear normal, they fail to respond to signals delivered by way of the TCR.[94,95] In a few cases, hypomorphic *ZAP70* mutations have been associated with delayed onset of the disease and manifestations of immune dysregulation (skin rash, wheezing, eosinophilia).[96,97] Treatment is based on HSCT.

CD8α Deficiency. CD8 molecules are expressed on the cell surface as either a CD8α_2 homodimer or a CD8αβ heterodimer. CD8α (gene *CD8A*) deficiency is a rare autosomal recessive disorder characterized by lack of circulating CD8+ lymphocytes and by an increased number of CD3+CD4−CD8− cells that express markers of effector cytotoxic T lymphocytes (CD11b, CD57). The disease is reported here because of some phenotypic similarities (reduced number of CD8+ cells) with ZAP-70 deficiency; however, clinical manifestations are distinct and more similar to MHC class I deficiency, with recurrent respiratory infections and delayed diagnosis.[98]

Other Forms of Combined Immunodeficiency with Variable Presentation

A number of primary immunodeficiencies may have a variable clinical phenotype; in some cases, patients affected with these disorders may present with clinical and laboratory features suggestive of a combined immunodeficiency.

Macrophage Stimulating 1 Deficiency

Macrophage stimulating 1 (MST1), also known as serine threonine kinase 4 (STK4), is a molecule that controls apoptosis and survival of naïve T lymphocytes by inducing expression of FOXO1, a transcription factor that induces expression of the IL-7R. MST1 deficiency is associated with recurrent infections, immune dysregulation, a moderate degree of neutropenia, and congenital heart disease. Viral infections are particularly common and include warts, molluscum contagiosum, and EBV-driven lymphoproliferative disease. The number of naïve T cells is

markedly decreased, and there is an expansion of TEMRA cells, associated with a restricted T cell repertoire. T lymphocytes show increased apoptosis and reduced proliferation to mitogens. There is also an increased proportion of transitional B lymphocytes, with reduced number of memory B cells.[99,100]

Dedicator of Cytokinesis 8 Deficiency

Dedicator of cytokinesis 8 (DOCK8) is a guanine nucleotide exchange factor that activates Cdc42 and participates at intracellular signaling in lymphoid and dendritic cells. *DOCK8* mutations cause an autosomal recessive form of combined immunodeficiency with hyper-IgE (this is also known as hyper-IgE syndrome type 2).[101,102] Patients suffer from chronic viral cutaneous infections (warts, molluscum contagiosum), recurrent skin abscesses and cellulitis, respiratory tract infections, candidiasis, eczema and other manifestations of severe allergy, autoimmunity (cytopenias, central nervous system [CNS] vasculitis), and an increased risk of malignancy (epithelial cell carcinoma, lymphomas, leiomyosarcoma). The disease has a severe prognosis with high mortality rate; treatment is based on HSCT.[103]

Immunologic abnormalities include T-cell lymphopenia with impaired thymopoiesis, a low number of naïve CD8+ cells, and accumulation of TEMRA lymphocytes. T cell proliferation to mitogens and antigens is often reduced, especially within CD8+ lymphocytes. Ig abnormalities include elevated serum IgE and low levels of IgM, and B cell responses to TLR agonists are compromised.[104] Immunologic memory is defective in both T- and B-cell compartments. In most cases, the genetic defect is represented by large intragenic deletions.[102]

Coronin-1A Deficiency

The Coronin-1A protein inhibits F-actin formation in T lymphocytes and thereby modulates cytoskeleton rearrangement and T-cell activation. Coronin-1A deficiency causes a combined immunodeficiency with recurrent and severe infections, including severe varicella and

EBV-driven lymphoproliferation.[105,106] Developmental delay has also been observed, possibly reflecting a role for Coronin-1A in the CNS.[105] There is profound T-cell lymphopenia, with reduced survival of T lymphocytes and impaired in vitro proliferation to mitogens and antigens. HSCT can cure the immunologic abnormalities and the increased susceptibility to infections.[105]

Veno-Occlusive Disease with Immunodeficiency Syndrome

Veno-occlusive disease with immunodeficiency (VODI) syndrome is an autosomal recessive condition characterized by severe infections (often including *Pneumocystis jiroveci* and CMV infection) and hepatomegaly with abnormalities of liver function and evidence of veno-occlusive disease on liver biopsy.[107] Cerebrospinal leukodystrophy has been reported in several patients.[108] Immunologic abnormalities include T- and B-cell lymphopenia, poor T-cell function, severe hypogammaglobulinemia, and lack of memory B lymphocytes.[108] If untreated, the disease is often fatal within the first years of life. Administration of intravenous immunoglobulin (IVIG) and antimicrobial prophylaxis may prolong survival, but the only curative approach is represented by HSCT.[109] Recurrence of veno-occlusive disease after HSCT has been reported.[108] VODI was initially described in patients of Lebanese descent, but the disease has been reported in other ethnic groups as well. The disease is caused by mutations of *SP110* encoding for a nuclear body protein that is thought to have a role in regulation of gene transcription.[107]

Immunodeficiencies Caused by Defects of Calcium-Release Activated Channels

On TCR-mediated signaling, Ca^{++} is mobilized from endoplasmic reticulum (ER) stores. This depletion is sensed by stromal interacting molecule 1 (STIM1), which oligomerizes and binds to the ORAI proteins that form the calcium-release activated channels (CRACs) on the cell surface, thereby permitting influx of Ca^{++}, activation of transcription factors (e.g., nuclear factor of activated T cells), cytokine production, T-cell proliferation, and induction of effector T cell responses. Mutations of *STIM1* and *ORAI1* genes in humans account for autosomal recessive combined immunodeficiencies with recurrent infections, signs of ectodermal dystrophy, nonprogressive myopathy (reflecting a role of CRACs in muscle cells).[110,111] Autoimmune manifestations (cytopenias, lymphadenopathy, and splenomegaly) may also be observed, especially in patients with STIM1 deficiency.[111] Kaposi sarcoma due to human herpesvirus 8 (HHV-8) infection has been reported.[112] The absolute lymphocyte count is normal, with preserved distribution of major lymphocyte subsets. However, in vitro proliferation to mitogens and antigens is impaired, and cell-mediated cytotoxicity and cytokine production are also affected.

Magnesium Transporter Protein 1 Deficiency

Magnesium transporter protein 1 (MAGT1) is an X-linked disease characterized by severe chronic viral infections, chronic diarrhea, and EBV-driven lymphoproliferative disease.[113] Immunologic abnormalities include CD4 lymphopenia and impaired T cell proliferation to CD3 stimulation. The *MAGT1* gene encodes for a membrane-associated Mg^{++} transporter. Female carriers have a skewed pattern of X chromosome inactivation in circulating T lymphocytes, suggesting that Mg^{++} signaling plays an important role in T lymphocyte development and survival.

Caspase Recruitment Domain Family Member 11 Deficiency

Caspase recruitment domain family member 11 (CARD11) is a scaffold protein that interacts with B-cell lymphoma 10 and mucosa-associated lymphoid tissue lymphoma translocation gene 1 proteins, thereby inducing activation of the canonical nuclear factor κB (NF-κB) pathway in lymphocytes. Biallelic loss of function mutations of *CARD11* are associated with a combined immunodeficiency, marked by increased susceptibility to opportunistic infections and hypogammaglobulinemia.[114] The number and distribution of T lymphocytes are preserved, other than for a reduced number of Treg cells; by contrast, there is expansion of transitional B lymphocytes and reduction of mature naïve and memory B lymphocytes. Moreover, in vitro activation of T and B cells with phorbol myristate acetate is severely impaired, and proliferation of T lymphocytes in response to stimulation by way of CD3/CD28 is abrogated. On in vitro activation, production of IL-2 by T cells and of interferon IFN-γ by NK cells is decreased.[114]

IL-21 Receptor Deficiency

IL-21 regulates proliferation of lymphocytes, differentiation of T helper 17 (Th17) cells, maturation of B cells into plasmablasts, and induction of NK cell cytotoxicity. IL-21 receptor (IL-21R) defects have been identified in four patients from two kindreds whose clinical phenotype included respiratory infections, chronic diarrhea, failure to thrive, and severe liver and biliary tract disease caused by infection with *Cryptosporidium* organisms.[115] The number of T, B, and NK lymphocytes is normal, but the proportion of switched memory B cells is reduced. Serum IgG levels are low or slightly subnormal, but IgE is elevated. Antibody responses to T-dependent and T-independent antigens are decreased. On in vitro activation with CD40 ligand (CD40L) and IL-21, B lymphocytes from the patients show reduced proliferation and defective class switch recombination. NK cytotoxic activity is markedly decreased. T cells proliferate normally in response to stimulation by CD3 and CD28 but fail to produce IL-17 and IL-22. Proliferation to antigens in vitro is impaired.[115]

MANAGEMENT OF COMBINED IMMUNODEFICIENCY

Diagnostic Approach

Suspicion of SCID or other forms of combined immunodeficiency is prompted by clinical symptoms, family history, or positive results of screening assays. In particular, newborn screening for SCID can be performed by quantifying levels of TCR excision circles (TRECs; see

Fig. 24-3 legend) in dried blood spots collected at birth.[116] TRECs are a by-product of rearrangement of TCR genes during intrathymic T-cell development. In patients with SCID, TREC levels are extremely low or absent as a result of lack of significant thymic T-cell output.[117] Indeed, since newborn screening for SCID has been started in various parts of the United States, several cases of SCID have been identified at birth in otherwise healthy-looking newborns.[118] However, it is not clear yet whether determination of TREC levels at birth may also reliably identify other forms (and which ones) of combined immunodeficiency with residual T-cell development. Tandem mass spectrometry can also be used for newborn screening of ADA deficiency[119] and may also identify subjects with residual levels of ADA activity, who could otherwise be missed by the TREC-based assay.[120]

Quantification of TRECs represents an important, yet nonspecific, indicator of a possible severe T-cell immunodeficiency, the diagnosis of which must be confirmed by appropriate immunophenotypic, functional, and molecular tests. Flow cytometry, looking at the distribution and absolute number of the major T-cell subsets, B and NK lymphocytes, may provide important information. Determination of naïve (CD45RA+CD62L+) and activated/memory (CD45RO+ CD62L−) T lymphocytes should be included in the diagnostic panel to correctly identify patients with maternal T-cell engraftment or with leaky SCID and expansion of in vivo activated, activated T cells. Functional tests include in vitro proliferation to mitogens (PHA, anti-CD3 monoclonal antibody) and antigens (provided that the patient has been exposed to these through immunization or natural infection). Ultimately, identification of the specific disease-causing mutation(s) may permit molecular diagnosis of the disease.

Hematopoietic Stem Cell Transplantation

Identification of a patient with SCID should be considered a pediatric emergency.[121] Children with this disorder are so prone to infections that extreme measures must be taken to protect them from microbial invasion. Before newborn screening for SCID became a reality, most patients were already infected when initially evaluated and required aggressive interventions to keep their clinical course from running inexorably downhill. After full immunologic evaluation has been performed (as expeditiously as possible), these patients should begin receiving IVIG infusions. Prophylaxis for *P. jiroveci* pneumonia is indicated for all patients.

Although alternative therapies may work for some patients (e.g., PEG-ADA for ADA deficiency), the definitive treatment for the great majority of patients with SCID and other combined immunodeficiencies is HSCT. A variety of sources have been used for stem cells, including HLA-identical sibling donors, haploidentical related donors (usually parents), unrelated donors, and umbilical cord blood.[122,123] Transplantation from a matched sibling donor in patients with SCID does not require conditioning and is associated with excellent survival and long-term immune reconstitution. Patients with SCID who lack a matched sibling donor may receive HSCT from one of their haploidentical parents, most often the mother. In this case, mature T lymphocytes must be removed from the graft to prevent graft-versus-host disease. T cell–depleted HSCT from a haploidentical donor for SCID may be performed without or with pretransplant chemotherapy. Unconditioned T cell–depleted haploidentical transplantation leads to long-term T-cell engraftment[124]; however, B- and NK-cell engraftment is rarely achieved, and lifelong use of IVIG may be needed, especially in patients who lack B cells (e.g., defects of VDJ recombination) or those whose genetic defects compromise B-cell function (γc, JAK3 defects).[125] Use of chemotherapy may allow stem cell engraftment (and hence also permit reconstitution of B- and NK-cell immunity); however, it is also associated with toxicity. In a large series, overall survival in SCID patients transplanted after the year 2000 was 90% when HLA-matched siblings served as donors and 66% after haploidentical HSCT.[123] However, when transplantation is performed in infants younger than 3.5 months of age, survival is greater than 95%, even after haploidentical donors,[126] thus justifying newborn screening for SCID based on quantification of TRECs at birth.[118]

HSCT is also the mainstay of treatment for other forms of combined immunodeficiency with presence of residual or normal number of autologous T lymphocytes. In such cases, however, pretransplant conditioning must be used to achieve engraftment. Overall survival after HSCT for these conditions is less satisfactory than in patients with SCID, being approximately 80% from matched siblings and 50% from haploidentical donors.[123]

Gene Therapy

Gene therapy for the treatment of human disease was first attempted in patients with ADA deficiency.[127,128] A functional copy of the *ADA* gene in a retroviral vector was transduced into populations of mature T cells or bone marrow cells. Transduced cells expressed normal levels of ADA and showed normal function in vitro. However, clinical efficacy was difficult to assess in these early attempts because adjunctive therapy with PEG-ADA was mandated on ethical grounds, even after the re-introduction of transduced cells into patients. More recently, gene therapy for ADA deficiency has been performed by transducing hematopoietic stem cells without concurrent in vivo administration of PEG-ADA[31,129]; use of submyeloablative doses of busulfan has permitted robust engraftment and long-term immune reconstitution in the vast majority of the patients.[31,32,129] However, the absolute T-cell count remains suboptimal in many patients, possibly reflecting irreversible thymic damage caused by toxic adenosine derivatives.

The earliest "complete" success of gene therapy is considered to have occurred with XSCID.[130,131] Hematopoietic stem cells were transduced ex vivo with a retroviral vector carrying a functional copy of the γ_c gene and then infused into patients without any conditioning chemotherapy. Twenty patients have been treated in this manner. Most patients have exhibited rapid and persistent reconstitution of T cell–mediated immunity. Reconstitution of B-cell immunity has been achieved only in some patients. The therapy appears to be less effective if performed later in life, probably because of deterioration of the thymic rudiment over time.[132]

Unfortunately, 5 of the 20 infants with XSCID treated by gene therapy have developed leukemia, which was fatal in one. Leukemias were caused by insertional mutagenesis. The vector integrated within or near oncogenes (in particular, *LMO2*) and the strong enhancers contained in the viral long terminal repeats (LTRs) caused oncogene transactivation and uncontrolled cell proliferation.[133,134] Novel clinical trials, based on self-inactivating retroviral and lentiviral vectors in which expression of the γ_c gene is driven by weaker cellular promoters (instead of the strong viral LTRs), are currently under way in Europe and in the United States.

IMMUNODEFICIENCY SYNDROMES

The term *syndromic immunodeficiencies* has been coined to describe the occurrence of abnormal development or function of the immune system leading to susceptibility to infection, autoimmunity, or malignancy in the setting of a genetically determined disorder with characteristic features of altered development or function of other organ systems or the body as a whole. Here we will review several disorders with prominent immune dysfunction. These diseases and their associated genes are listed in Table 24-4. Space does not permit a detailed description of the tremendous variety of syndromes that have been associated with immunodeficiency. Interested readers are referred to an excellent review on this topic.[135]

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS) is an X-linked disease characterized by eczema, immunodeficiency, and thrombocytopenia.[136] Bloody diarrhea is often seen and may be the initial feature. Eczema may be mild or exuberant; staphylococcal superinfection is common. Recurrent otitis media and sinopulmonary infections occur frequently, and opportunistic infections are also seen. In addition, autoimmune hemolytic anemia, vasculitis, inflammatory bowel disease, glomerulonephritis, and other autoimmune processes have been frequently observed in WAS. Patients most often die as a result of overwhelming infection or massive hemorrhage. Those who avoid these complications have a greatly increased risk for lymphoma, many of which are EBV positive. There is also an increased risk of aortic aneurysms.[136,137]

Variability of the clinical phenotype has been reported, and a clinical score has been developed to reflect this phenotypic heterogeneity.[136] A milder form of the disease, characterized by thrombocytopenia with mild eczema and lack of severe infections, is also referred to as *isolated X-linked thrombocytopenia (XLT)*.[138] Although XLT patients have better survival rates compared with patients who have classical WAS, nonetheless they have a significant risk of complications (e.g., autoimmunity, hemorrhage). In some cases, the thrombocytopenia may even be intermittent.[139] On the other hand, patients who present early in life with very profound ($<10 \times 10^9$/L) and persistent thrombocytopenia have very poor outcomes.[140]

TABLE 24-4 Cellular Immunodeficiency Syndromes and Their Associated Gene Defects.

Syndrome	Gene
Wiskott-Aldrich syndrome	*WAS*
DiGeorge syndrome	del22q11, *TBX1*
DNA repair defects:	
Ataxia-telangiectasia	*ATM*
Nijmegen breakage syndrome and others	*ATLD, NBS1, PMS2*
Disorders of chromosome instability:	
Bloom syndrome	*BLM*
ICF syndrome	*DNMT3B, ZBTB24*
Disorders of pigmentary dilution:	
Chédiak-Higashi syndrome	*LYST*
Griscelli syndrome type 2	*RAB27A*
Hermansky-Pudlak syndromes types 2 and 9	*AP3B1, PLDN*
Defects of the NF-κB pathway	*IKBKG, IKBA*
Defect in Toll-like receptor signaling	*IRAK4, MYD88*
WHIM syndrome	*CXCR4*
Hyper IgE syndromes	*STAT3, TYK2*
Chronic mucocutaneous candidiasis	*CARD9, IL17RA, IL17F, STAT1*
Immunodeficiencies with skeletal abnormalities:	
Cartilage-hair hypoplasia	*RMRP*
Schimke immuno-osseous dysplasia	*SMARCAL1*
Disorders of vitamin metabolism	*TCN2, MTHFD1*

ICF, Instability facial anomalies; *WHIM,* warts, hypogammaglobulinemia, infections, and myelokathexis.

Platelets are small, do not function normally, and are also cleared more rapidly (although the number of bone marrow megakaryocytes is normal or even increased).[136] In the appropriate clinical context, measurement of platelet size confirms the diagnosis. In normal individuals platelet volume is 7.1 to 10.5 fL, with a diameter of 2.3 ± 0.12 μm, whereas platelets from patients with WAS have volumes ranging from 3.8 to 5.0 fL with diameters of 1.82 ± 0.12 μm. The low platelet volume distinguishes the thrombocytopenia of WAS from immune thrombocytopenic purpura (ITP), in which platelets are often large. However, ITP may develop in as many as 20% of patients with WAS.

The mainstay of treatment for WAS is HSCT.[141] Without HSCT, survival beyond adolescence is uncommon. The rates for 5-year survival after HSCT for WAS approximates 90% for transplants performed after year 2000. Optimal results (survival >95%) are obtained after HSCT from matched siblings, but significantly improved outcome has been also achieved after HSCT from unrelated donors and even mismatched related donors.[141] Mixed chimerism is associated with increased risk of autoimmunity after transplant.[141]

Pretransplant morbidity and mortality rates may be reduced with regular infusions of IVIG and antibiotic prophylaxis.[136] Blood products, when needed, should be irradiated and tested for CMV. Splenectomy often increases the platelet count, although immune thrombocytopenia may later supervene. Moreover, splenectomy markedly increases the risk of overwhelming infections. Immunosuppressive agents may be needed to treat autoimmune complications of the disease.[136]

The immune defects in WAS are variable.[136,142] Immune function may be normal in early infancy, but it gradually wanes. T cell numbers may be decreased, and T cells have diminished, but not absent, responses to mitogens and antigens in vitro. T cells in WAS will also proliferate in response to nonspecific activating stimuli such as phorbol esters and calcium ionophores but show a striking absence of reactivity to immobilized antibodies directed against the CD3 complex of the TCR. The diversity of the T-cell repertoire appears normal throughout childhood, but it may become more restricted with consequent worsening immunodeficiency in adulthood.[143]

Serum levels of IgA and IgE are often elevated, whereas IgM may be low; however, increased serum IgM is associated with an increased risk of autoimmunity and worse outcome.[144] Isohemagglutinins and specific antibody responses to polysaccharide antigens are also diminished. Although the frequency of class-switched B cells (i.e., those not expressing IgM) appears to be normal, there are fewer memory B cells expressing CD27, thus indicating some alteration in B-cell activation in germinal centers that could underlie or contribute to the humoral immunodeficiency.[145] Finally, dendritic cells and monocytes show impaired formation of podosomes and defective directional migration in response to chemotactic signals.[142]

The gene defective in WAS has been identified; its official name is *WAS,* and its product is designated the WAS protein (WASP). The same gene is defective in XLT,[146] as well as in X-linked congenital severe neutropenia.[147] The latter disease is due to activating *WAS* mutations; its phenotype is very different from WAS and includes chronic neutropenia with a differentiation block in the bone marrow and an increased risk of myelodysplasia.[147,148]

WASP interacts with several intracellular partners, including the WASP-interacting protein (WIP), Rho family guanosine triphosphatases, and the Arp2/3 complex, which leads to reorganization of the actin cytoskeleton in response to activating stimuli in lymphoid and myeloid cells.[142]

There is a good, yet imperfect, genotype-phenotype correlation in WAS.[149] In particular, XLT is more often associated with residual expression of WASP and with missense mutations in exons 1 and 2 of the *WAS* gene that correspond to a domain of WASP that interacts with WIP. This interaction stabilizes WASP, thereby explaining reduced levels of WASP detected in cells from patients with XLT.[150] In contrast, the more severe phenotypes are associated with complete absence of protein or with expression of truncated, nonfunctional forms of WASP. Somatic mutations allowing expression of WASP in some cell populations (more often, in CD8+ T lymphocytes) have been frequently reported in WAS.[151] However, the impact of this phenomenon on clinical phenotype remains unclear.

The diagnosis of WAS is facilitated by analysis of WASP expression by flow cytometry or Western-blotting; however, this approach may miss patients who express a mutant form of the protein. Ultimately, mutation analysis is required to confirm the diagnosis.[136] Female carriers of WAS are generally asymptomatic and have normal platelet counts but show nonrandom X-chromosome inactivation in lymphocytes and granulocytes.[152] Occasionally, occurrence of WAS or XLT in females has been reported as the result of various mechanisms, including extreme lyonization favoring the mutant X chromosome,[153,154] random X-chromosome inactivation,[155,156] or *WAS* gene mutation on both X chromosomes.[157]

WAS Protein-interacting Protein Deficiency

A single case of a female patient with mutations of the *WIPF1* gene, encoding WIP, has been reported. The phenotype included recurrent infections, thrombocytopenia, defective T-cell proliferation and chemotaxis, and impaired NK cell function. No expression of the WIP and WASP proteins was detected in circulating cells.[158]

DiGeorge Syndrome

DiGeorge syndrome (DGS) arises as a result of a failure of migration of neural crest cells into the third and fourth pharyngeal pouches. Patients display a characteristic facies, cardiac defects, parathyroid hormone deficiency, and varied immune defects.[159,160] The facies consists of hypertelorism; micrognathia; short philtrum; and low-set, posteriorly rotated ears with small pinnae. Cardiac defects are varied. Type B interrupted aortic arch is the most common and is associated with DGS in 50% of patients with this defect. Truncus arteriosus and other conotruncal anomalies are also common. Structural anomalies of the airways have likewise been found in some patients, as well as dysphagia secondary to laryngoesophageal dysmotility. The bilateral paired parathyroid glands are normally adherent to the thymus. Thus these organs are affected together in this disease. The parathyroid deficiency is often more pronounced than the thymic defect; hypocalcemic tetany is one of the more common initial symptoms of DGS. Even small islands of ectopic thymus tissue may permit the development of sufficient T cells for immune competence. Neuropsychiatric problems and some degree of cognitive impairment are seen in many patients and become more prominent during adulthood.[161]

Partial and complete forms of DGS have been distinguished on the basis of clinical and immunologic characteristics.[159,160] In the complete form the thymus is absent or severely hypoplastic.[162] These patients have absent or markedly decreased numbers of T lymphocytes. B cells are present, but specific antibody production is impaired. Some patients may have erythroderma, similar to that seen in OS. In this condition, also referred to as *atypical complete DGS,* oligoclonal, activated (CD45RO+) tissue-infiltrating T lymphocytes are detected.[162] If untreated, complete DGS is most often fatal in early childhood; patients die as a result of hypocalcemia, cardiac complications, infection, or a combination of these causes.

The occurrence of partial forms of DGS outnumbers that of the complete form by about 100 : 1. T-cell number and function in most patients are varied and presumably correlate with the amount of ectopic thymus tissue present. Immune function in patients with complete DGS does not improve; patients with partial DGS may have less immunodeficiency as they get older. In some cases, the diagnosis has been made in adults being evaluated for hypoparathyroidism and hypocalcemia.[163] Humoral immunity is generally intact in patients with partial DGS; however, IgA deficiency and defective antibody production have been reported.[160] An increase in atopic dermatitis and asthma has been reported in individuals with 22q11 deletion.[164] Autoimmunity (especially ITP, other cytopenias, juvenile arthritis, and celiac disease) is observed in 10% of the patients.[165]

In various series, between 55% and 90% of patients with DGS have 2 to 3 megabase deletions involving chromosome 22q11.2.[166,167] Deletions in the same region are found in patients with a spectrum of phenotypically overlapping conditions, including velocardiofacial syndrome and conotruncal anomaly face syndrome, and in some patients with isolated cardiac defects. There is heterogeneity in expression of the DGS phenotype, even in monozygotic twins. Approximately 40 genes are present in the deleted regions in DGS, and the contributions of each to the phenotype are only beginning to be understood.[168] *TBX1* encodes a member of a family (T-box) of transcription factors. Mice that are heterozygous for deletion of this gene have a phenotype that is variable but often very similar to that of humans with DGS, including thymic and parathyroid hypoplasia, cardiac outflow tract abnormalities, and abnormal facial structure.[169] Two truncating and three missense mutations in *TBX1* have been found in a few patients with DGS or velocardiofacial syndrome and no detectable 22q11.2 deletion.[170-172] Interestingly, the missense mutations were found to result in gain of function, suggesting that increased TBX1 activity may phenocopy *TBX1* loss of function or haploinsufficiency.[172] Some patients with DGS have deletions on chromosome 10p13-p14.[173]

Although recurrent infections can be observed in up to 25% to 30% of patients with DGS, severe viral and opportunistic infections are very rare, other than in patients with complete DGS. Live viral vaccines may be administered safely to the great majority of patients.[160] By contrast, complete DGS has a severe prognosis, but it can be treated successfully by thymus transplantation. Immunosuppression is needed to control severe immune dysregulation in patients with complete atypical DGS while preparing for thymus transplantation.[174] In a recent study 43 of 60 patients (72%) treated with this procedure were reported to be alive at a median of 4.7 years after transplantation, and they attained an increase in T-cell count with improved function, although absolute naïve CD4+ and CD8+ counts remained below the 10th percentile in most of them.[174] HSCT from matched donors may also provide some immune reconstitution through homeostatic proliferation of mature T lymphocytes contained in the graft; however, in a series of 17 patients with complete DGS treated by HSCT, overall survival rate was only 41% and the count of naïve CD4+ cells remained very low.[175]

FOXN1 Deficiency

The transcription factor FOXN1 plays a critical role in development of the thymus and eccrine glands. *FOXN1* mutations in humans cause athymia, profound T-cell lymphopenia, alopecia totalis, and nail dystrophy, fully resembling the "nude" phenotype observed in *Foxn1*-mutated mice.[176] There is complete lack of CD4+ lymphocytes, whereas a low number of oligoclonal CD8+ cells may be present.[177] Similar to DGS, reconstitution of T-cell immunity can be achieved with thymic transplantation.[178] Alternatively, HSCT from HLA-identical siblings may provide some immune reconstitution through homeostatic proliferation of T lymphocytes contained in the graft.[179]

Ataxia-Telangiectasia

Ataxia-telangiectasia (AT) is an autosomal recessive disorder with an estimated incidence of 1 in 20,000 U.S. Caucasian births (95% confidence interval, 1 in 2500 to 700,000).[180] AT is characterized by progressive cerebellar ataxia, oculocutaneous telangiectasia, and immunodeficiency.[181] Associated features are an increased incidence of lymphoma and sensitivity to radiation. Impairment in motor development may be noted early in the disease course and is progressive. Walking may be delayed until 16 to 18 months of age or later. Telangiectases of conjunctival and cutaneous vessels do not appear until children are 3 to 5 years of age. The cutaneous lesions are found mainly on the pinnae and in skin creases. Immunodeficiency will occur in approximately 70% of patients. Manifestation of the immunodeficiency is quite varied, but it is often seen as recurrent sinopulmonary bacterial infections. Granulomatous lesions are frequently seen and may reflect immune dysregulation.[182] Growth retardation is a prominent feature in many patients and has been associated with decreases in insulin-like growth factor I and its binding protein.[183]

The median age at death in patients with AT is approximately 19 to 25 years.[184,185] Many patients die as a result of progressive pulmonary disease caused by repeated infection. Possibly, noninfectious and ultimately fatal interstitial lung disease may also occur in approximately 25% of patients.[186] The lifetime risk for malignancies in AT is 30% to 40%; 85% of the cancers are acute leukemias or lymphomas.[187] Elevated serum levels of α-fetoprotein (AFP) are found in more than 95% of patients with AT and have diagnostic value in the appropriate clinical context; however, levels of AFP are physiologically higher at birth and for the first two years.[188]

T and B cell lymphopenia is a well-recognized, though variable, feature of AT in adulthood but may also be present at birth and be detected by abnormal TREC levels at newborn screening for SCID.[189] T cells bearing the TCRγδ constitute up to 50% or more of the total number of T cells in patients with AT.[190] These cells make up fewer than 10% of peripheral T cells in normal individuals. Cutaneous delayed hypersensitivity responses, as well as results of in vitro assays of T-cell function, are often depressed. Varying degrees of humoral immunodeficiency are common. IgA deficiency occurs in two thirds of patients. Decreased levels of IgG2, IgG4, and IgE are also common, yet approximately 10% to 30% of the patients have increased IgM.[191,192] Impaired specific antibody responses, particularly to pneumococcal polysaccharide antigens, have also been noted in AT patients.[193]

The gene that is defective in AT is designated *ATM* (AT mutated). *ATM* has critical roles in regulation of the cell cycle: It is involved in the detection of DNA damage and in the initiation of repair.[194] There is a marked delay in induction of the tumor suppressors p53 and *BRCA1* after exposure of AT cells to radiation. Even low-dose radiation leads to significantly greater DNA damage in AT fibroblasts and lymphoblasts than in normal individuals.[195] *ATM* mutations are associated with impaired lymphocyte proliferation.[196] Lymphocytes of patients with AT also show a remarkable number of chromosomal translocations and inversions. These changes predominantly involve the loci that rearrange to generate mature Ig (2p12, 22q12, and 14q32) and TCR (7p15, 7q35, and 14q11) genes and reflect defective repair of the double-stranded breaks produced as part of the physiologic gene rearrangement process during lymphocyte development. ATM is also involved in class-switch recombination (CSR), and this may explain reduced levels of IgG, IgA, and IgE seen in patients.[197]

No definitive cure is available for AT. Medical management aimed at preventing and treating infections (antibiotics, Ig), tumor surveillance, and neurorehabilitation represent the mainstays of treatment.[188] Very recently, some improvement of neurologic signs has been observed on administration of betamethasone, possibly reflecting antiinflammatory and antioxidant activity of glucocorticoids in the CNS.[198]

Whether pathologic changes result from the heterozygous carrier state of AT remains a subject of controversy. Carriers heterozygous for *ATM* mutations have none of the classic clinical manifestations of AT; however, the sensitivity of their DNA to radiation is increased, and several reports suggest that AT heterozygotes have an increased rate of a variety of malignancies, such as breast cancer.[199]

OTHER IMMUNODEFICIENCIES ASSOCIATED WITH DEFECTIVE MECHANISMS OF DNA REPAIR

The Nijmegen breakage syndrome is a disorder of chromosome fragility with autosomal recessive inheritance.[200] The phenotype is similar to that of AT and consists of growth retardation, microcephaly, immunodeficiency, sensitivity to radiation, and a high rate of lymphoma. The affected gene is designated *NBS1*. Nibrin, its protein product, is another substrate of ATM in the cellular response to ionizing radiation. Absence of nibrin function leads to disruption of mechanisms of DNA repair, but it does not appear to result in abnormal function of cell cycle checkpoints. Another similar syndrome, AT-like disorder, results from mutations of the gene *MRE11A*, which encodes another ATM substrate.[201]

Postmeiotic segregation 2 (PMS2) and MutS homologue 6 (MSH6) are components of the DNA mismatch repair pathway. PMS2 deficiency is associated with increased occurrence of malignancies, café-au-lait spots, and defective CSR.[202] MSH6 deficiency is also associated with increased risk of cancer and defective maturation of antibody responses, with impairment of CSR and a skewed pattern (higher rate of transitions) of somatic hypermutation.[203]

IMMUNODEFICIENCIES WITH CHROMOSOMAL INSTABILITY

Bloom syndrome is characterized by chromosomal instability with increased sister chromatid exchange and homologous chromosome translocations and is associated with increased frequency of infections, low levels of IgM, and impaired delayed-type hypersensitivity responses. The disease is caused by mutations of the *BLM* gene, encoding for a helicase.[204]

The immunodeficiency-centromeric instability facial anomalies syndrome is characterized by hypogammaglobulinemia, facial dysmorphisms, and branching of chromosomes 1, 9, and 16. The disease may be caused by mutations in the DNA methyl transferase 3B *(DNMT3B)*[205] or in the zinc-finger- and-BTB (bric-a-brac, tramtrack, broad complex)-domain-containing 24 *(ZBTB24)* genes.[206]

Mutations of the mini-chromosome maintenance-deficient 4 *(MCM4)* gene have been identified in patients with recurrent and severe viral infections (in particular, caused by herpes simplex virus 1 [HSV-1], varicella zoster virus [VZV] and CMV), growth retardation, adrenal insufficiency, and selective NK cell deficiency with lack of the CD56^{dim} NK subset.[207,208] The disease is inherited as autosomal recessive trait. MCM4 is a component of a multiprotein complex required for both initiation and elongation of eukaryotic DNA replication.[209] *MCM4* mutations were shown to cause abnormalities of cell cycle, with increased proportion of fibroblasts in G2/M and S phases of cell cycle and an aberrant (>4n) DNA content, and genomic instability.[207]

PIGMENTARY DILUTION DISORDERS

Pigmentary dilution disorders include diseases in which abnormalities in melanosome trafficking within cells lead to characteristic pale skin and silvery-gray or ashen hair. Several forms of pigmentary dilution disorders are also characterized by a variable degree of immune deficiency, in particular impaired cell-mediated cytotoxicity. In these conditions inability to clear virus-infected cells leads to persistent and exaggerated inflammatory responses with macrophage activation, release of proinflammatory cytokines, and continuous activation of infiltrating CD8$^+$ T cells that secrete high amounts of IFN-γ and cause tissue damage. Fever, hepatosplenomegaly, lymphadenopathy, and cytopenia caused by impaired hematopoiesis in the bone marrow and hemophagocytosis are typical manifestations of immune activation during the so-called accelerated phase of the disease. Impaired cytotoxicity of virus-infected cells reflects defective trafficking, docking or release of cytolytic granules in NK cells, and cytotoxic T cells. This defect parallels defects of melanosome trafficking.

Chédiak-Higashi syndrome is characterized by partial albinism, peripheral neuropathy, and increased risk of viral infections. Neutropenia is often present and may facilitate bacterial infections. Recognition of "giant" lysosomes in leukocytes facilitates the diagnosis.[210] The disease is caused by mutation of the lysosomal trafficking regulator *(LYST)* gene.[211] The precise mechanism by which the LYST protein works is not known, although it is thought to regulate trafficking of intracellular vesicles. HSCT is the only definitive treatment, but it does not prevent possible progression of neurologic complications.

Griscelli syndrome (GS) type 2 also associates partial albinism and immunodeficiency with increased susceptibility to infections, fever, and cytopenia. The disease is caused by mutations of the *RAB27A* gene, which encodes for a protein that permits docking of the cytolytic granules to the cell membrane.[212] In contrast, GS type 1 (caused by mutations of the *MYO5A* gene, encoding for the myosin Va protein) and GS type 3 (due to mutations of the gene encoding for the melanin chaperone melanophilin) are characterized by hypopigmentation without immunodeficiency.

Hermansky-Pudlak syndrome type 2 (HPS2) is characterized by oculocutaneous albinism, bleeding diathesis, neutropenia, interstitial lung disease, and recurrent infections.[213] Patients are at increased risk of hemophagocytosis. The disease is caused by mutations of the β subunit of the adaptor-related protein complex 3 (gene *AP3B1*) involved in sorting of proteins to the lysosomes.[214] Patients with HPS9, which is caused by mutations of the pallidin *(PLDN)* gene,[215] present with hypopigmentation and nystagmus; recurrent cutaneous infections also have been reported.[216]

MUTATIONS OF THE NUCLEAR FACTOR κ-B PATHWAY

NF-κB is a transcription factor that is critical for the activation of numerous genes on leukocyte stimulation.[217] Activity of this factor is regulated by an inhibitor known as IκB. Phosphorylation of IκB by IκB kinase (IKK) leads to IκB degradation and liberates active NF-κB. IKK is composed of three subunits, α, β, and γ; the latter is also known as the NF-κB essential modulator (NEMO). The gene encoding NEMO is on the X chromosome. Null mutations in this gene are incompatible with life for male subjects and lead to the X-linked dominant disease incontinentia pigmenti in females. Certain mutations that allow partial NEMO function are associated with an immunologic phenotype that may have some similarities to hyper-IgM. Along with a combined immunodeficiency, these patients may exhibit hypohidrotic ectodermal dysplasia and lymphedema with osteopetrosis.[217-220] Distinct hypomorphic mutations define specific disease characteristics, thus establishing genotype-phenotype correlation, albeit imperfectly.[218] Somatic mosaicism in T lymphocytes has been detected in a significant proportion of males with NEMO deficiency, providing evidence for selective advantage for NEMO-expressing T cells in vivo.[221] However, whether this may affect the disease phenotype is not clear.

Patients may suffer opportunistic-type disseminated viral infections and *P. jiroveci* pneumonia and are also highly susceptible to atypical mycobacterial infections. Inflammatory bowel disease is also frequently seen, reflecting a role of NF-κB in controlling epithelial integrity and the interaction between the mucosal immune system and gut microflora.[222] Finally, lymphedema and osteopetrosis may also be part of the disease phenotype.[220]

Most patients are hypogammaglobulinemic and have impaired vaccine responses (especially to polysaccharide antigens). Peripheral blood lymphocyte subsets and in vitro measures of lymphocyte function may be unremarkable or variably diminished; NK cell cytotoxicity may be impaired. Signaling by way of TLRs is also affected. Therapy with gamma globulin and antibiotic prophylaxis is essential. Despite these measures, infections may still occur. HSCT may cure the immunologic abnormalities and resolve increased susceptibility to infections, but inflammatory bowel disease may persist, along with extra-immune manifestations of the disease.[223]

A few patients have been found to have a similar phenotype as a result of a so-called hypermorphic (gain of function) mutation of the IκBα chain.[224,225] In this situation the IκBα is resistant to phosphorylation by IKK and cannot be dissociated, degraded, and induced to release NF-κB so that it may translocate to the nucleus to activate transcription.

DEFECTS OF TOLL-LIKE RECEPTOR SIGNALING

IRAK-4 and Myd88 are components of a complex mediating signaling downstream of all TLRs (except TLR3).[226] Patients with *IRAK4* or *MYD88* mutations have severe, invasive bacterial infections such as meningitis, bacteremia, septic arthritis, deep-tissue abscesses, and osteomyelitis with gram-positive organisms (predominantly *Staphylococcus aureus* and *Staphylococcus pneumoniae*.[227-229] Less severe skin and respiratory infections also occur frequently. Most patients begin to exhibit infections in early childhood, but these wane significantly in frequency and intensity in the second decade of life. Most patients have impaired antibody responses to pneumococcal polysaccharides, but other routine tests of immune function are normal. Many patients have high levels of all Ig isotypes, possibly owing to immune stimulation by repeated bacterial infections. Signaling is impaired through all TLRs other than TLR3. Management is mainly with antibiotic prophylaxis and IgG therapy.

THE SYNDROME OF WARTS, HYPOGAMMAGLOBULINEMIA, INFECTIONS, AND MYELOKATHEXIS

The syndrome of warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM syndrome) is an autosomal dominant disorder of leukocyte trafficking caused by mutations of the chemokine receptor CXCR4.[230] Patients carry heterozygous mutations in the intracellular tail of CXCR4 that prevent interaction with β-arrestin, thus allowing continuous signaling induced by CXCR4 ligand, CXCL12. This signal retains mature neutrophils in the bone marrow (myelokathexis) and alters trafficking of B and T lymphocytes, causing lymphopenia.[231]

Impairment of cellular immunity and defective number of plasmacytoid dendritic cells (which are the major source of IFN-γ) cause warts, and neutropenia and hypogammaglobulinemia account for recurrent bacterial infections that mostly affect the respiratory tract.[231,232] The number of switched memory B cells is reduced, and there is oligoclonality of the antibody repertoire.[233] Gamma globulin replacement therapy generally reduces the rate of infection. The CXCR4 antagonist AMD3100 (plerixafor) corrects neutropenia and lymphopenia.[234]

HYPERIMMUNOGLOBULIN E SYNDROME CAUSED BY *STAT3* MUTATIONS

Hyper-IgE syndrome (HIES, often designated type 1) was initially described in 1972 in patients with severe sinopulmonary bacterial infections, severe skin superinfections with *S. aureus* on a chronic eczematous eruption (for which the disease is also known as *Job syndrome*), and susceptibility to *Aspergillus fumigatus* pneumonitis with pneumatocele formation.[235] Additional manifestations include asymmetric or coarse facial features, delayed shedding of primary teeth, bone fragility and fractures, scoliosis, and keratoconjunctivitis.[236] Patients show increased susceptibility to nonfilamentous molds, such as *P. jiroveci* pneumonia and in particular chronic mucocutaneous candidiasis (CMC). There is an increased rate of malignancies, especially non-Hodgkin lymphoma.[236] Cardiovascular anomalies have been described in recent years and include aneurysms, in particular of the carotids, cerebral arteries, and coronary arteries, and may lead to additional complications such as myocardial infarction.[237] Inheritance of this form of HIES is autosomal dominant, but many cases represent sporadic presentations. The disease is caused by heterozygous dominant-negative mutations of the *STAT3* gene that encodes for a transcription factor involved in signaling from a multitude of receptors.[238,239] In particular, STAT3 is required for the development of T_h17 cells, which secrete IL-17 and IL-22, two cytokines that play an important role in defense against candida and in promoting secretion of antimicrobial peptides by bronchial epithelial cells.[240]

The major immunologic findings are elevated serum levels of IgE (3000 to >50,000 IU/mL) and eosinophilia. Along with a deficiency of T_h17 cells, a reduced number of memory (CD27+) B lymphocytes also have been reported. The diagnosis is established on clinical and laboratory grounds; a scoring system[241] has been developed that may be helpful, especially if used in combination with demonstration of lack of T_h17 cells.[242] Management of HIES caused by *STAT3* mutations is mainly by skin care and antimicrobial prophylaxis against *S. aureus*. The role of antifungal prophylaxis is controversial, but it may be helpful in patients with CMC. HIES patients may lack classical signs and symptoms of infection, such as fever. Therefore careful physical examination, medical history, and imaging studies are needed to evaluate, diagnose, and treat any infections. Controversial results have been obtained after HSCT.[243,244]

AUTOSOMAL RECESSIVE HYPER-IMMUNOGLOBULIN E SYNDROME CAUSED BY *TYK2* MUTATIONS

Two distinct forms of autosomal recessive HIES are known. Of these, DOCK8 deficiency has been discussed in the preceding section "Other Combined Immunodeficiencies with Variable Presentation." Two patients with autosomal recessive HIES caused by mutations of *TYK2*, a member of the JAK family of tyrosine kinases involved in intracellular signaling, have been reported. The first patient presented with atopy, elevated serum IgE, and susceptibility to infections sustained by *S. aureus*, BCG, *Salmonella* organisms, and viruses.[245] The second patient suffered from disseminated BCG infection, neurobrucellosis, and cutaneous herpes zoster but had normal serum IgE and did not develop atopy.[246]

CHRONIC MUCOCUTANEOUS CANDIDIASIS

CMC affecting the nails, skin, and mucosa is the clinical hallmark of three distinct genetic disorders that affect IL-17–dependent immunity.[247] These include complete, autosomal recessive deficiency of IL-17 receptor α chain *(IL17RA)*,[248] partial autosomal dominant IL-17F deficiency,[248] and heterozygous gain-of-function mutations of signal transducer and activator of transcription 1 *(STAT1)*.[249,250] The latter represents the most common cause of isolated CMC. Mutations of caspase recruitment domain-containing protein 9 *(CARD9)* gene, encoding a cytosolic adaptor molecule involved in intracellular signaling in cells recognizing fungi, also affect development of T_h17 cells and cause CMC; however, CARD9-deficient patients are also at increased risk of disseminated *Candida* infections as well as of other fungal infections.[251] Deficiency of T_h17 cells accounts for CMC also in other forms of primary immunodeficiency, including T-cell deficiencies, HIES, and autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED).

IMMUNODEFICIENCIES WITH SKELETAL ABNORMALITIES

Cartilage-hair hypoplasia (CHH) is an autosomal recessive disease characterized by short-limbed dwarfism with metaphyseal dysplasia, sparse and fair hair, and joint hypermotility. Dyserythropoietic anemia and a variable degree of immunodeficiency are present in 80% of the patients. A minority of subjects also present with Hirschsprung disease. There is a 6% to 10% rate of malignancies, especially lymphoma and basal cell carcinoma. The disease has a higher prevalence among Finnish and Amish populations[252] and is caused by mutations in the *RMRP* gene that encodes for the untranslated RNA component of the mitochondrial RNA-processing endoribonuclease[253] that is involved in multiple functions, including ribosomal and messenger RNA processing, mitochondrial DNA replication, and negative regulation of target RNA transcripts on interaction with TERT (telomerase reverse transcriptase).[252]

The immunodeficiency of CHH is characterized by increased frequency of infections. Severe and persistent viral infections (EBV, CMV, HSV, and VZV) and fungal infections may occur, in addition to recurrent respiratory infections. Granulomatous lesions affecting the skin and other tissues have been described in several patients.[254] Laboratory tests reveal a variable degree of immune dysfunction that predominantly affects T cells. In rare cases, immunodeficiency is very severe and may resemble SCID, "leaky" SCID with reduced number of CD8+ lymphocytes, or OS.[255,256] Irrespective of the severity of the clinical phenotype, thymopoiesis is reduced, and there is T-cell lymphopenia. Moreover, T lymphocytes show abnormalities of cell cycle progression and an increased rate of apoptosis.[257] HSCT is an effective form of treatment for patients with a severe clinical phenotype.[258]

Schimke immuno-osseous dysplasia is an autosomal recessive disease characterized by spondyloepiphyseal dysplasia, focal glomerulosclerosis leading to progressive renal failure, and T-cell immunodeficiency.[259] There is T cell lymphopenia, with an increased proportion of activated/memory T cells and of TCRγδ-expressing T lymphocytes. The disease is caused by mutations of the *SMARCAL1* gene, which encodes for a chromatin remodeling protein.[260]

IMMUNODEFICIENCIES ASSOCIATED WITH DISORDERS OF FOLATE AND COBALAMIN METABOLISM

Inborn errors of folate and cobalamin metabolism may associate with varying degrees of immunodeficiency. In particular, genetically determined defects in vitamin B_{12} metabolism are associated with megaloblastic anemia, neutropenia, and neurologic symptoms with seizures and developmental delay.[261] Transcobalamin II (gene *TCN2*) deficiency causes neutropenia leading to recurrent bacterial infections.[262] Severe lymphopenia is observed in patients with deficiency of methionine synthase, causing a SCID-like phenotype with severe viral and bacterial infections.[263] Mutations of proton-coupled folate transporter that impede folate absorption through the gastrointestinal mucosa are also associated with extreme lymphopenia and clinical features of SCID.[264] Mutations of the *MTHFD1* gene that encodes for a trifunctional protein essential for processing of single-carbon folate derivatives cause SCID with decreased number of T, B, and NK lymphocytes, which is associated with megaloblastic anemia, leukopenia, atypical hemolytic uremic syndrome, and neurologic abnormalities. Parenteral supplementation therapy is beneficial.[265]

GATA2 DEFICIENCY

In 2010 Vinh and coworkers[266] reported on a series of patients with a distinct clinical phenotype characterized by onset in late childhood or adulthood, susceptibility to disseminated nontuberculous mycobacterial disease, recurrent and severe viral infections (especially those caused by papillomavirus and herpesviruses), and fungal infections. There is increased risk of myelodysplasia and malignancies, including acute myeloid leukemia, squamous cell carcinoma, and EBV-positive leiomyosarcoma. Pulmonary alveolar proteinosis and primary lymphedema have been observed in several patients.[266-269]

Typical laboratory features include profound monocytopenia, severe reduction in the number of B and NK lymphocytes (in particular, of the $CD56^{bright}$ subset) and dendritic cells and elevated levels of fms-like tyrosine kinase ligand (Flt3L).[266,267,270] Depletion of regulatory T cells also has been reported.[267] Examination of the bone marrow reveals hypocellularity, often associated with multilineage dysplasia and cytogenetic abnormalities, including monosomy 7 and trisomy 8. In vitro IL-12 and IFN-γ production in response to stimulation with LPS is markedly reduced,[267,268] suggesting that disruption of the IL-12/IFN-γ axis may contribute to the increased occurrence of mycobacterial disease.

The disease has been referred to as *MonoMAC syndrome* (to indicate the monocytopenia and susceptibility to nontuberculous mycobacterial infections)[266,268] or DCML (dendritic cells, monocytes, B and NK lymphocytes) deficiency[267] and has been shown to be caused by heterozygous, loss-of-function mutations of the *GATA2* gene.[271-273] GATA-2 is a transcription factor that contains two highly conserved zinc finger domains that mediate protein-DNA and protein-protein interactions and is required for stem cell homeostasis,[274] lymphatic vessel development,[273] and the maturation and homeostasis of NK lymphocytes.[270] Disease-causing mutations also include intronic deletions and point mutations in regulatory regions of the gene that affect *GATA2* transcript levels.[275] Both autosomal dominant inheritance and sporadic presentation have been reported. If untreated, the disease has a severe prognosis, with death occurring in adulthood as a result of infections or malignancies. Nonmyeloablative HSCT has been successfully performed in several patients, with reconstitution of the number of monocyte, B-cell, and NK-cell populations and reversal of the clinical phenotype.[276]

IMMUNODEFICIENCIES WITH IMMUNE DYSREGULATION

Although autoimmune and inflammatory manifestations may be seen in a large number of primary immunodeficiencies, they represent the main feature in some. The pathophysiology of these disorders may reflect a variety of mechanisms, including impairment of central and peripheral tolerance and chronic immune activation associated with the inability to clear infections. These disorders and their associated genes are listed in Table 24-5.

AUTOIMMUNE POLYENDOCRINOPATHY-CANDIDIASIS-ECTODERMAL DYSTROPHY SYNDROME

APECED syndrome represents the prototypic disorder associated with impairment of central T-cell tolerance.

TABLE 24-5 Immunodeficiency Syndromes Associated with Dysregulation

Syndrome	Gene
Autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED)	*AIRE*
Immune dysregulation polyendocrinopathy X-linked (IPEX)	*FOXP3*
Defects of IL-2 signaling	*IL2RA, STAT5B*
Autoimmune lymphoproliferative syndrome (ALPS)	*CASP8, CASP10, FAS, FASLG, KRAS, NRAS*
Other	*ITCH*

APECED is inherited as an autosomal recessive trait and is characterized by autoimmune hypoparathyroidism, Addison disease, and CMC. Patients are also prone to other autoimmune manifestations, such as hepatitis, alopecia, ovarian failure, and hypothyroidism. There is an increased incidence of oral squamous cell carcinoma, and fulminant autoimmune hepatitis. The disease is caused by mutations in the gene *AIRE* (autoimmune regulator) encoding a transcription factor expressed by medullary thymic epithelial cells (mTECs).[277,278] AIRE promotes expression of tissue-specific antigens that are presented by mTECs and thymic dendritic cells to nascent T lymphocytes.[279] High-affinity recognition of self peptides leads to deletion of self-reactive T cells. Therefore mutations of the *AIRE* gene compromise the mechanism of central tolerance and result in APECED, which is associated with production of multiple autoantibody specificities.[280] Interestingly, autoantibody production in patients with APECED is not restricted to AIRE-dependent self-antigens but also includes antibodies to interferon-α and β[281] as well as IL-17 and IL-22.[282,283] Defective T_h17-dependent immune responses may account for chronic mucocutaneous candidiasis in this disease.

IMMUNE DYSREGULATION POLYENDOCRINOPATHY ENTEROPATHY X-LINKED SYNDROME

Treg cells maintain peripheral T cell tolerance by suppressing self-reactive T lymphocytes that have escaped central tolerance.[284] Generation of Treg cells is controlled by the transcription factor FOXP3.[285] Mutations of the *FOXP3* gene cause immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome.[286,287] IPEX is characterized by severe early-onset autoimmune manifestations that involve the gut (causing intractable diarrhea), pancreas (diabetes), the skin, and other organs. Lymphoproliferation and cytopenias are also very common. Delayed presentations have been also observed.[288] Patients with IPEX require immune suppression, but the only definitive treatment currently available is allogeneic HSCT.[289]

DEFECTS OF IL-2–MEDIATED SIGNALING

IL-2–mediated signaling is important to maintain immune homeostasis and support the function of Treg lymphocytes. Mutations in the IL2RA gene, which encodes CD25, the α chain of the IL-2R, cause immunodeficiency with IPEX-like immune dysregulation.[290,291] The clinical phenotype is marked by severe diarrhea, failure to thrive, CMV infection, chronic lung disease, lymphadenopathy, splenomegaly, and autoimmunity (diabetes mellitus, autoimmune hepatitis). Poor in vitro T-cell function that could not be corrected with exogenous IL-2 was demonstrated. The number of $FOXP3^+$ cells was preserved in patients with CD25 deficiency; however, secretion of IL-10, a cytokine with immunosuppressive activity, was impaired,[290] possibly accounting for the autoimmune manifestations of the disease.

Mutations of the signal transduced and activator of transcription 5B *(STAT5B)* gene, which encodes a transcription factor activated by IL-2 signaling, cause an autosomal recessive form of immunodeficiency with immune dysregulation. Because STAT5B is also activated in response to growth hormone receptor stimulation, patients with STAT5B deficiency also show growth failure with growth hormone insensitivity.[292,293]

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Apoptosis of self-reactive lymphocytes is another important mechanism to prevent autoimmunity in the periphery and may be induced either through the extrinsic, Fas-dependent pathway or through induction of the mitochondrial pathway in response to cell damage and cytokine (e.g., IL-2) starvation. Both pathways converge on caspase 9 and downstream effector caspases 3 and 7, causing apoptosis. Autoimmune lymphoproliferative syndrome (ALPS) is characterized by lymphadenopathy, splenomegaly, and autoimmune cytopenias and an increased risk of developing lymphoma. Infiltrative lymphoproliferative disease may also cause organ-specific complications (glomerulonephritis, hepatitis, encephalitis, uveitis, interstitial pulmonary disease). There is a characteristic expansion of CD3+TCRαβ+CD4−CD8− double-negative T cells (DNTs).[294]

Most patients are heterozygous for a mutation in the *FAS* gene; in such families the disease is inherited as an autosomal dominant trait with variable penetrance. Somatic mutations in *FAS* are another common cause of the disease.[295,296] More rarely, patients may show biallelic mutations.

Other rare causes of ALPS are represented by mutations of genes encoding Fas ligand (FasL),[297] FADD,[298] caspase 8,[299] and caspase 10,[300] all of which are involved in the Fas-mediated signaling pathway leading to apoptosis. The number of DNTs is only marginally elevated in patients with caspase 8 deficiency.

In addition to an increased proportion of DNTs, other biomarkers that may facilitate the diagnosis of ALPS and that are associated especially with *FAS* mutations include elevated serum levels of vitamin B_{12}, soluble FasL, IL-10, and IL-18. Hypergammaglobulinemia is common. Moreover, patients with ALPS caused by *FAS* mutation frequently have a reduced number of memory (CD27+) B lymphocytes.[301]

Defects of the "intrinsic" (mitochondrial) pathway of apoptosis leading to ALPS include gain-of-function mutations of *NRAS*[302] and somatic mutations of *KRAS*,[303,304] but these variants do not result in an increased number of DNTs.

Management of ALPS includes use of immunosuppressive drugs (steroids, mycophenolate mofetil, sirolimus) to control autoimmune manifestations and regular monitoring of lymphoproliferation by computed tomography scanning or positron emission tomography for surveillance of lymphoma. Splenectomy may improve the cytopenias but is associated with a marked increase of sepsis. Chronic cytopenias tend to improve over time; HSCT should be reserved for very severe clinical presentations with autoimmune disease refractory to treatment.[305]

ITCH DEFICIENCY

Mutations of the E3 ubiquitin ligase ITCH have been shown to cause multisystem autoimmune disease in affected individuals from a large Amish kindred.[306] Characteristic clinical features include failure to thrive, hepatosplenomegaly, multiorgan autoimmune manifestations (hypothyroidism, hepatitis, diabetes, enteropathy), chronic lung disease, developmental delay, dysmorphic features, and hypotonia. Dysfunction of E3 ubiquitin ligases have been shown to lead to indiscriminate T cell activation, loss of tolerance to self-antigens and accumulation of autoreactive B lymphocytes.[307]

IMMUNODEFICIENCIES WITH IMPAIRED CELL-MEDIATED CYTOTOXICITY

CD8+ cytotoxic T lymphocytes (CTLs) and NK cells play a critical role in antiviral immune defense through two mechanisms: Fas-mediated apoptosis of virus-infected cells and release of cytolytic granules. In resting CTLs and NK lymphocytes, cytotoxic proteins are contained in endosomal secretory granules. On activation of CTLs and NK lymphocytes, lytic granules polarize toward the immune synapse, dock, and fuse with the cell membrane of the effector cell. Multimers of perforin form pores through which CTLs and NK cells release cytotoxic proteins (granzyme B, granulolysin) into virus-infected target cells, causing activation of caspases and apoptosis of target cells.[308]

Defects in this process are responsible for various forms of familial hemophagocytic lymphohistiocytosis.[309] Defective cell-mediated cytotoxicity is also observed in several forms of pigmentary dilution disorders (discussed previously). Finally, selective susceptibility to EBV infection is at the basis of various forms of lymphoproliferative syndrome. These diseases and their associated genes are listed in Table 24-6.

TABLE 24-6 Immunodeficiency Syndromes with Impaired Cytotoxicity

Syndrome	Gene
Familial hemophagocytic lymphohistiocytosis	*PRF1, STX11, STXBP2, UNC13D*
X-linked lymphoproliferative syndromes	*BIRC4, SH2D1A*
Other	*CD16, CD27, ITK*

FAMILIAL HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

Familial hemophagocytic lymphohistiocytosis (FHL) includes a heterogeneous group of monogenic disorders characterized by impaired cell-mediated cytotoxicity. In patients with FHL, the inability to clear viral infections causes persistent activation of CD8+ and NK lymphocytes, with production of high amounts of IFN-α and -β and of proinflammatory cytokines (tumor necrosis factor-alpha [TNF-α], IL-6).[309] Clinical features of FHL include recurrent episodes of high fever, pancytopenia, liver and spleen enlargement, and signs of neurologic involvement. The diagnostic criteria were revised in 2007.[310] Elevated serum levels of triglycerides, ferritin, and soluble CD25 and decreased levels of fibrinogen and poor NK function are typical laboratory findings. If left untreated, FHL is rapidly fatal. Severe bacterial and fungal infections and multiple organ failure are the main causes of death. Treatment should be aimed at eradicating the underlying infection while suppressing immune activation at the same time. Corticosteroids, cyclosporine A, etoposide, and antithymocyte globulin are often effective in tempering immune activation.[311] However, relapses are common, and the only curative treatment is represented by HSCT. In particular, reduced intensity conditioning has shown excellent efficacy and limited toxicity.[312]

The genetic defect has been identified for four forms of FHL so far, and all of them are inherited as autosomal recessive traits. Perforin deficiency accounts for approximately 30% of all cases of FHL. It is caused by mutations of the *PRF1* gene that prevent expression or correct assembly of perforin multimers that form pores through which cytolytic enzymes are released into target cells.[313] Mutations of the *UNC13D* gene, encoding for Munc13-4, impair priming of the cytolytic granules, which is necessary for their fusion with the cell membrane. *UNC13D* mutations represent the most common form of FHL (30% to 40% of all cases).[314] Defects of the Syntaxin 11 *(STX11)* gene affect granule exocytosis.[315] Finally, FHL may also be caused by defects of Munc18-2, a protein partner of STX11 encoded by the Syntaxin binding protein 2 *(STXBP2)* gene.[316]

X-LINKED LYMPHOPROLIFERATIVE DISEASE

X-linked lymphoproliferative (XLP) disease is characterized by unique susceptibility to severe complications after EBV infection in male subjects. Two genetically distinct forms are known. In XLP1 the disease is caused by mutations of the SH2 domain containing protein 1 A *(SH2D1A)* gene, encoding for a small adapter protein (SLAM-associated protein, or SAP) involved in intracellular signaling in T and NK lymphocytes.[317,318] In particular, SAP binds to CD244 (a SLAM family member) expressed by NK lymphocytes. EBV-infected B cells express high levels of CD48, the CD244 ligand. On CD244/CD48 binding, SAP participates at intracellular signaling and promotes NK cytolytic activity against EBV-infected target cells. In the absence of SAP, NK cytolytic activity is impaired.[319] SAP is also important for the function of follicular helper T cells that promote maturation of antibody responses.[320] XLP2 is caused by mutations of the *BIRC4* gene, which encodes for the X-linked inhibitor of apoptosis (XIAP) protein.[321]

XLP1 and XLP2 have partially overlapping clinical features. Hemophagocytic lymphohistiocytosis (HLH) subsequent to primary EBV infection is a prominent sign at clinical presentation in both diseases. XLP1 may manifest with fatal infectious mononucleosis, aplastic anemia, pulmonary lymphoid granulomatosis with vasculitis, and lymphoma.[322] A proportion of XLP1 patients who survive primary EBV infection will develop hypogammaglobulinemia, which in some cases is associated with elevated levels of IgM or IgA. Some patients may have a clinical and laboratory phenotype consistent with common variable immunodeficiency (CVID, discussed later). Functional activity of NK and CTLs is impaired. Finally, patients with XLP1 lack NKT lymphocytes.[323] Without HSCT, 62.5% of the patients survive (and most of them require Ig replacement); however, poor survival rates (less than 20%) have been observed in patients without transplants who have features of HLH. HSCT may cure approximately 80% of XLP1 patients, but poorer outcome (50% survival) has been observed if HLH is present.[322]

In contrast, XLP2 causes recurrent episodes of HLH, with or without EBV infection.[323] Patients with XLP2 are not at increased risk of lymphoma; on the other hand, inflammatory bowel disease is frequently observed.[324] Definitive treatment of XLP2 is also based on HSCT; however, use of a myeloablative conditioning regimen is associated with high mortality.[325]

IL-2 INDUCIBLE TYROSINE KINASE DEFICIENCY

Interleukin-2 inducible tyrosine kinase (ITK) is a nonreceptor tyrosine kinase that modulates the strength of intracellular signaling in T lymphocytes on TCR-induced activation. Patients with ITK deficiency are susceptible to EBV-driven lymphoproliferative disease (often involving the lungs as well), Hodgkin lymphoma, hypogammaglobulinemia, autoimmunity, and HLH.[326] The disease is inherited as an autosomal recessive trait. There is a reduced number of naïve CD4+ lymphocytes and of NKT cells. Allogeneic HSCT may cure the disease.

CD27 DEFICIENCY

CD27 is a member of the TNF receptor family and is broadly expressed on the surface of various lymphocyte subsets. By interacting with CD70, it promotes generation and maintenance of T-cell memory. It is also commonly used as a marker of memory B lymphocytes. CD27 deficiency has been identified in some patients presenting with severe EBV infection. Lymphoma and secondary hypogammaglobulinemia have been reported in some of these patients. HSCT represents a curative form of treatment.[327,328]

CD16 DEFICIENCY

One of the mechanisms by which NK lymphocytes mediate killing of target cells is antibody-dependent cellular cytotoxicity (ADCC), whereby antibody-bound target cells come in contact with NK lymphocytes through binding of the Fc region of IgG molecules to a specific receptor (FcγRIIIa, also known as CD16) expressed on the surface of NK lymphocytes. Homozygosity for the Leu66His amino acid substitution in CD16 causes deficient spontaneous NK cell-mediated cytotoxicity but surprisingly leaves ADCC intact. Expression of CD2, a co-activating NK cell receptor, is decreased, affecting intracellular signaling in NK lymphocytes. Recurrent and severe herpesvirus infections are the clinical hallmark of this condition.[329]

IMMUNODEFICIENCIES WITH SELECTIVE PREDISPOSITION TO PATHOGENS

Most forms of primary immunodeficiencies are characterized by susceptibility to a broad range of pathogens, whose nature (bacteria, viruses, fungi, protozoa) reflects the underlying immune defect. However, in the last two decades it has become clear that certain gene defects that affect the immune system may lead to selective predisposition to a narrow group of pathogens. These findings have supported the genetic theory of infectious diseases, whereby life-threatening infections early in life may in fact be caused by inborn errors of immunity.[330] These disorders and their associated genes are listed in Table 24-7.

Mendelian Susceptibility to Mycobacterial Diseases

The designation *Mendelian susceptibility to mycobacterial diseases (MSMD)* refers to a group of PIDDs characterized mainly by selective susceptibility to infection with mycobacteria including both *Mycobacterium tuberculosis* and many atypical species.[331-334] Patients

TABLE 24-7 Immunodeficiencies with Selective Predisposition to Pathogens

Syndrome	Gene
Mendelian susceptibility to mycobacterial disease	*IFNGR1, IFNGR2, IL12B, IL12RB1, STAT1*
Epidermodysplasia verruciformis	*TMC6, TMC8*
Trypanosomiasis	*APOL1*

are also susceptible to disseminated infections with *Salmonella* species. There are no other consistent clinical manifestations, and all routine screening tests of humoral and cellular immunity are normal. The vast majority of these patients harbor mutations in one of five genes that encode elements in a signaling cascade involving IFN-γ and IL-12. IL-12 is produced by mononuclear cells in response to stimulation by way of TLRs and other pattern recognition receptors. IL-12 stimulates T_h1 differentiation, and mature T_h1 cells and NK cells produce IFN-γ. IFN-γ then acts on mononuclear cells to promote intracellular killing of phagocytosed organisms. In the absence of the normal operation of this sequence, macrophages are not able to kill ingested mycobacteria or *Salmonella* organisms, and severe infection results. Thus far, mutations have been found in the genes encoding the IL-12 p40 subunit *(IL12B),* the β1 chain of the IL-12 receptor *(IL12RB1),* both chains of the IFN-γ receptor (*IFNGR1, IFNGR2),* and the STAT1 signal transducing molecule which mediates signaling of the IFN-γ receptor.[331-334] Most cases show autosomal recessive inheritance, but a few specific mutations of *IFNGR1* may exhibit autosomal dominant inheritance. Acquired forms of susceptibility to mycobacterial infection have been ascribed to autoantibodies to IFN-γ.

Therapy for MSMD is mainly through aggressive treatment of infections when they occur and prophylaxis for selected individuals who may relapse frequently. For patients with hypomorphic (partly functional) mutations of *IFNGR1,* IFN-γ supplementation may be beneficial.

Epidermodysplasia Verruciformis

Mutations in the genes *TMC6* (transmembrane channel-like 6) and *TMC8* give rise to epidermodysplasia verruciformis (EV). These genes were previously called *EVER1* and *EVER2*, respectively. EV exhibits autosomal recessive inheritance, and affected individuals are susceptible to persistent skin infection only by HPV.[335,336] There is a high rate of malignant transformation in the skin, but there are no other infectious susceptibilities or clinical manifestations of the disease. Acquired EV has been associated with human immunodeficiency virus (HIV) infection.[337,338]

Herpes Simplex Encephalitis

HSVs are prevalent in the general population and are capable of causing disseminated severe and even fatal infections in patients with profound T-cell defects (discussed earlier). However, in rare cases individuals are susceptible specifically to encephalitis caused by HSV, in the absence of any other organ or system involvement.[339-343] To date, mutations in five distinct genes have been associated with this clinical entity: TLR3 *(TLR3), UNC93B1, TRAF3, TICAM1* (previously known as *TRIF*), and *TBK1*. All of the proteins encoded by these pathways interact in transducing responses by way of TLR3 (and in some cases also TLR4) with the common result of a failure to produce sufficient amounts of type 1 interferons in response to HSV infection in the brain. Inheritance varies according to the genes and the specific mutations involved. Thus far, mutations in *UNC93B1* have shown exclusively autosomal recessive inheritance, whereas mutations of *TRAF3* and *TBK1* have exhibited exclusively autosomal dominant inheritance. Mutations of *TLR3* and *TICAM1* have shown either dominant or recessive inheritance depending on the specific lesion.

Susceptibility to Trypanosomiasis

Trypanosomes are single-cell (protozoan) organisms causing endemic infections in many parts of the world. *Trypanosoma cruzi* is the causative agent of Chagas disease, and it is estimated that approximately 10 million people in South America harbor this parasite, most being asymptomatic. Subspecies of *Trypanosoma brucei* are responsible for sleeping sickness, and it is estimated that more than 60 million individuals in Africa harbor this organism. Most individuals are protected from progression of disease by apolipoprotein L1 (APOL1), which can lyse the *T. brucei* plasma membrane and kill the organism. Some strains of trypanosomes have become more pathogenic by virtue of their resistance to APOL1 lysis.[344-348] Conversely, individuals who have mutations in their *APOL1* genes are more susceptible to trypanosome infection and severe disease. There are no known clinical consequences of deleterious *APOL1* mutations beyond susceptibility to *T. brucei*. However, isoforms of APOL1 selected through evolution for higher trypanosome lytic activity are risk factors for nondiabetic kidney disease in African-Americans.[349]

HUMORAL IMMUNODEFICIENCY

The humoral immunodeficiencies and their associated gene defects are listed in Table 24-8. These disorders are characterized by hypogammaglobulinemia or dysgammaglobulinemia, often together with relative deficiency of antibody responses to various forms of antigenic challenge.[3,4] Cellular immunity is generally intact. Humoral immunodeficiency is most commonly manifested by recurrent bacterial and viral infections of the upper and lower respiratory tract. Pyogenic skin infections, as well as meningitis, osteomyelitis, and other foci of infection, are also seen frequently. These infections are generally caused by the same organisms that are virulent in immunocompetent hosts, predominantly encapsulated bacteria such as *Streptococcus pneumoniae*, *Hemophilus influenzae, S. aureus*, and *Neisseria meningitidis*. Viral infections usually resolve normally in these patients, although a higher rate of recurrence with the same agent may be seen because there is impaired production of neutralizing antibodies or B-cell memory. The results of physical examination are not specific and show only the presence or sequelae of microbial infections. A relative paucity of peripheral lymphoid tissue may be noted in some patients, especially areas rich in B cells (e.g., tonsils). Studies of peripheral blood lymphocyte subsets are often normal; the number of B cells may be reduced in certain syndromes.

TABLE 24-8 Humoral Immunodeficiencies and Associated Gene Defects

Syndrome	Gene
X-linked (Bruton) agammaglobulinemia	*BTK*
Autosomal recessive agammaglobulinemias	*CD79A, CD79B, BLNK, IGHM, IGLL1, LRRC8, PIK3R2*

Common variable immunodeficiency	Undefined
Good syndrome	Undefined
Selective IgA deficiency	Undefined
IgG subclass deficiency	Undefined
Specific antibody deficiency with normal immunoglobulins	Undefined
Transient hypogammaglobulinemia of infancy	Undefined
Class-switch defects: CD40 ligand deficiency (X-linked HIM) CD40 deficiency B-cell–specific defects	 *TNFSF5* *TNFRSF5* *AICDA, UNG*

The Agammaglobulinemias

X-Linked Agammaglobulinemia

X-Linked agammaglobulinemia (XLA) is also known as *Bruton agammaglobulinemia* because Bruton provided the classic description of the disease in 1952.[350] Affected male subjects are often asymptomatic during the first months of life while they are protected by transplacentally acquired maternal antibodies. These antibodies fall to low levels by 6 to 9 months of age, and patients begin to experience recurrent bacterial infections.[351-353] Physical examination at any age often reveals a striking absence of tonsils and palpable lymphoid tissue. Serum Ig is absent or the level is extremely low; in addition, no B cells are found or their numbers are extremely low. Cellular immunity is completely intact. However, these patients are prone to the development of chronic enteroviral meningoencephalitis and vaccine-associated paralytic poliomyelitis, which suggests an important role for humoral immunity in the control of these infections. Moreover, patients may have arthropathy resembling rheumatic disease, which may be due to infection with *Mycoplasma* or *Ureaplasma* organisms. Other opportunistic infections, such as *P. jiroveci* pneumonia, are seen only rarely.

XLA is another example of an immunodeficiency caused by a defect in a signal transduction molecule. In fact, this protein tyrosine kinase is now known as Bruton tyrosine kinase ([Btk], Fig. 24-7).[351-353] It is expressed in B cells at all stages of development, as well as in cell lines derived from monocytes, macrophages, mast cells, and erythroid cells. A variety of *BTK* gene defects such as point mutations, deletions, and insertions have been described in patients with XLA. In most patients B-cell development is impeded at an early stage (the pro–B-cell to pre–B-cell transition).

BTK mutations account for approximately 85% of all cases of agammaglobulinemia.[354] *BTK* mutations have also been described in patients with "atypical" XLA who have low numbers of B cells and low-level antibody production.[351-353] In some patients with atypical XLA, CVID was misdiagnosed (discussed later) before discovery of the *BTK* defect.[355] In general, *BTK* mutations that permit the expression of small amounts of functional or partially functional Btk protein are associated with milder clinical phenotypes and slightly higher numbers of B cells in the circulation. [351-353] However, even siblings with identical mutations may show quite divergent phenotypes. Female carriers of XLA show nonrandom X-chromosome inactivation in their B cells.

Autosomal Recessive Agammaglobulinemias

Female patients with agammaglobulinemia and no B cells and males with a similar phenotype lacking *BTK* mutations have been described. These patients have forms of agammaglobulinemia with autosomal recessive inheritance that result from several distinct molecular defects,[354] including mutations of the Igμ heavy-chain locus, which prevents formation of the IgM heavy chain required for formation of the Ig receptors on pre-B cells and mature B cells (see Fig. 24-7). Defects of λ5 (a component of the

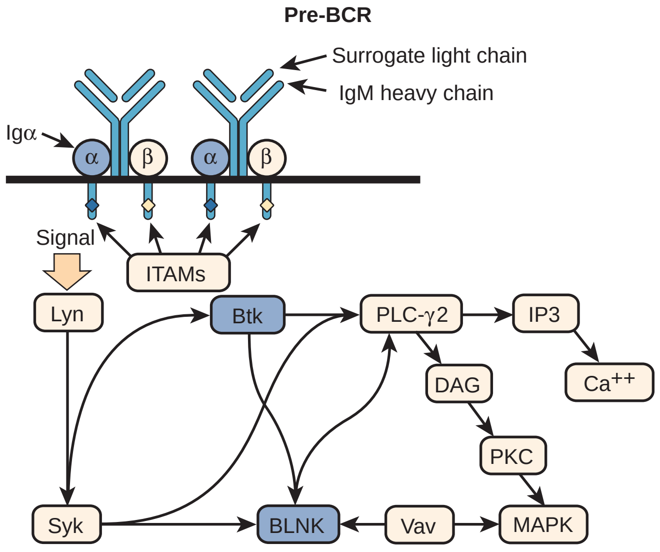

Figure 24-7 Signaling via the pre–B-cell receptor (Pre-BCR). The Pre-BCR is composed of an IgM heavy chain with a surrogate light-chain heterodimer (VpreB and λ5), along with a signaling heterodimer of Igα and Igβ. The immunoreceptor tyrosine-based activating motifs (*ITAMs*, see Fig. 24-5) recruit tyrosine kinases *(Lyn, Syk, Btk)* that initiate downstream signaling. The adapter proteins BLNK and Vav recruit additional signaling intermediates. Defects in components shown in blue lead to agammaglobulinemia by blocking pre-BCR signaling and interrupting B-cell development. *DAG,* Diacylglycerol; *IP3,* inositol triphosphate; *PKC,* protein kinase C; *PLC,* phospholipase C; *MAPK,* mitogen-activated protein kinase.

surrogate light chain) also prevent formation of the pre–B-cell Ig receptor required for B-cell development. Igα (CD79a) and Igβ are transmembrane molecules required for signal transduction by way of the pre–B-cell and mature B-cell Ig receptors. Lesions in these genes prevent Ig receptor signaling and B-cell development.[356] Defects in the signal transduction proteins BLNK (B-cell linker protein) and the p85 (β-regulatory) subunit of phosphoinositide 3′ (PI3) kinase (gene *PIK3R2*) have also been found.[354,357] Mutations in these molecules prevent intracellular signaling after ligation of the B-cell receptor. All these mutations arrest B-cell development at early stages in bone marrow.

One patient has been described with an apparent dominantly expressed translocation abrogating the function of the *LRRC8*) gene.[358] The function of the LRRC8 protein is not yet known; it is a member of a growing family of proteins of unknown function called the LRRC8 family, within the much larger and very diverse superfamily of leucine-rich repeat proteins. The female patient has agammaglobulinemia with arrest of B-cell development in bone marrow.

Other Predominantly Antibody Deficiency Syndromes

Common Variable Immunodeficiency

The diagnostic label of CVID encompasses an unknown number of conditions that are genetically and etiologically distinct but have in common late-onset humoral immunodeficiency, most often in the first or third decades of life.[359-363] Hypogammaglobulinemia and impaired specific antibody production are universal, by definition. Deficiency of IgA is very common in CVID.[364] IgM is also frequently affected; the pattern varies from one individual to another. The levels of particular isotypes in any patient are often static over time, but fluctuations may occur.

Patients with CVID resemble individuals with XLA (and other humoral immunodeficiencies) because they also have recurrent sinopulmonary bacterial infections. Chronic enteroviral infections, including meningoencephalitis, may also be seen in CVID. A form of granulocytic/lymphocytic interstitial lung disease occurs in a subset of patients and has been linked in some patients to HHV-8 infection.[365,366] More diffuse noncaseating granulomatous disease resembling sarcoidosis may be encountered in the skin or viscera. Additional manifestations include lung disease resembling asthma, chronic rhinitis, chronic giardiasis, and recurrent or chronic arthropathy. The apparent "atopic" symptoms usually occur in the absence of allergen-specific IgE.[367] Malabsorptive inflammatory bowel disease may occur.[368] A broad spectrum of autoimmune diseases may be associated, including a variety of cytopenias, arthritides, and vasculitides.[369,370] Widespread lymphoproliferation may cause splenomegaly, adenopathy, and intestinal lymphonodular hyperplasia.[371-373] Patients with CVID also have a higher incidence of gastrointestinal and lymphoid malignancies.[364] The relative risk for lymphoma has been estimated to be as much as 30- to 400-fold greater than that in the general population.

Memory B-cell subpopulations may be useful diagnostic and potentially prognostic markers in CVID.[363,374-379] Memory B cells express the CD27 (TNFRSF7) molecule. Naïve B cells express IgM and IgD but not CD27. Unswitched memory B cells (also called marginal zone cells) express IgM, IgD, and CD27. After class-switching in germinal centers, B cells cease expressing IgM and IgD and subsequently express "downstream" Ig isotypes such as IgG, IgA, and IgE (Fig. 24-8). Memory B cells after class-switching (switched memory B cells) are IgM^{-}IgD^{-}CD27^{+}. Additional subsets of B cells include transitional B cells (IgM^{high}CD38^{high}) and CD21^{low} B cells. Proportions of these peripheral B cell subtypes enumerated by flow cytometry correlate with clinical phenotypes. A more severe clinical phenotype with lower Ig and worse infections and increased granulomatous disease correlates with a decreased number of marginal zone and class-switched B cells. Granulomatous disease and splenomegaly also correlate with an expansion of CD21^{low} B cells. Increase in transitional B cells is associated with lymphadenopathy. Specific B cell subsets are developmentally regulated, and age-adjusted values should be used in these instances.[380-382]

Although cellular immune function is grossly preserved in the majority of patients with CVID, a variety of

Figure 24-8 Immunoglobulin (Ig) heavy-chain gene deletion haplotypes. The top line shows the order of the Ig constant region genes (e.g., M = IgM, etc.). The letters *ps* designate a pseudogene that is not expressed; numbers indicate subclasses. Six haplotypes have been defined (Roman numerals). In each haplotype the entire region indicated by the Xs is missing. *(Data from Lefranc MP, Hammarstrom L, Smith CI, Lefranc G: Gene deletions in the human immunoglobulin heavy chain constant region locus: molecular and immunological analysis.* Immunodefic Rev *2:265–281, 1991.)*

functional and phenotypic T-cell abnormalities are found in some.[359,382-385] These include reductions in peripheral blood T-cell populations, as well as functional defects such as reduced in vitro proliferative responses, defects in cytokine production, decreased T-helper cell function, abnormalities in T-cell signaling, diminished expression of the costimulatory molecule CD40L, decreased numbers of naïve T cells, increased suppressor T-cell function, and decreased numbers of regulatory T cells.

The genetic heterogeneity of CVID is beginning to yield to molecular biologic analysis. Several single-gene defects have been found in varying (small) proportions of patients with CVID (discussed later). It may also happen that individuals classified as having CVID (or a phenotype consistent with CVID) on clinical and laboratory grounds may be found to have mutations in genes characteristically associated with other primary immunodeficiencies. Such has been the case with some individuals with mutations in *BTK* (causative in XLA),[355] *SH2D1A* or *XIAP* (XLP disease),[386,387] and *TNFSF5* (CD40L, X-linked hyper-IgM syndrome).[388]

Functionally relevant polymporphisms in *TNFRSF13B* (encoding TACI) occur in approximately 1% of the general population. The most common are Cys104Arg (cysteine 104 replaced by arginine) and Ala181Glu. Approximately 10% of patients with CVID are heterozygous, and 1% are homozygous for these.[389-392] TACI is expressed on B cells and interacts with the ligands BAFF and APRIL expressed on macrophages and dendritic cells. These interactions have important roles in B-cell activation and Ig class switching. TACI polymorphisms are not entirely disease causing by themselves, but the presence of one of these TACI polymorphisms does appear to confer increased risk of lymphoproliferation and autoimmunity.[393]

The genetic determinants of CVID in the majority of patients may be more complex. A recent genome-wide association study revealed complex patterns.[394] The strongest associations were with the MHC locus and a family of disintegrin/metalloproteinase genes. However, there were at least 16 associated gene duplications or deletions together with many (≈100) unique intraexonic duplications or deletions. Furthermore, a complex genetic signature composed of more than 1000 single nucleotide polymorphisms was highly predictive of the CVID phenotype. How this heterogeneous genetic picture relates to the clinic manifestations of CVID is unknown.

Deficiency of Inducible T-Cell Costimulator

The inducible T-cell costimulator (ICOS) is expressed on T cells after stimulation. It interacts with a member of the B7 family of molecules known as ICOS ligand. Fewer than 20 patients worldwide have been found to have CVID associated with ICOS deficiency.[395] These patients may manifest recurrent respiratory and gastrointestinal infections in adulthood, panhypogammaglobulinemia and impaired vaccine responses, autoimmune disease (neutropenia), lymphoproliferation, and cancer (carcinoma of the vulva). Lymphoid tissues exhibit poorly formed germinal centers, and circulating switched memory B cells are markedly reduced.

CD19, CD21, and CD81 Deficiencies

CD19 is expressed on B cells and is a component of a receptor complex that contains CD21, a receptor for the complement fragment C3dg (it is also called complement receptor 2, or CR2, and it is the cellular receptor for EBV) along with a tetraspan molecule called TAPA1 (also CD81). Simultaneous cross-linking of the CD19/CD21/CD81 complex and the B-cell Ig receptor lowers the threshold for B-cell activation. Patients with defects of the *CD19*,[396,397] *CD21*,[398,399] or *CD81*[400] genes exhibit recurrent infections, hypogammaglobulinemia, and low levels of switched memory B cells. Autoimmunity and lymphoproliferation do not appear to be elements of the clinical presentations of these disorders.

BAFF Receptor Deficiency

Two siblings have been described with homozygous deletions in the *BAFFR* gene encoding the BAFF (B cell activating factor) receptor.[401] Both had low IgG, poor polysaccharide antibody response, and low memory B cells. However, only one sibling had recurrent infections. It is not clear why only one sibling was affected clinically, but variable penetrance is frequently observed in all forms of immunodeficiency.[4]

Good Syndrome

The occurrence of thymoma in the context of a clinical and immunologic picture very similar to that of CVID with low numbers of B cells and generally more severely impaired T-cell function has been designated Good syndrome.[402-406] The spectrum of bacterial sinopulmonary infections and pathogens is similar to those associated with the more prevalent forms of CVID. However, Good syndrome is associated more frequently with opportunistic infections, including mucocutaneous candidiasis, severe varicella-zoster virus infection, *P. jiroveci,* CMV, and recurrent HSV. Lymphadenopathy and splenomegaly, commonly seen in CVID, are not characteristic features of Good syndrome. Autoimmune disease is a frequent complication of Good syndrome, most notably pure red cell aplasia and neutropenia. Patients with Good syndrome also often suffer from chronic diarrhea of unclear etiology.

Panhypogammaglobulinemia is a consistent finding in Good syndrome.[402-406] Unlike the majority of patients with CVID, immunophenotypic analysis of peripheral blood lymphocytes frequently shows absent or very low numbers of B cells, reduced CD4+ T cells, absent cutaneous delayed hypersensitivity responses, and reduced in vitro T-cell response to mitogen. It is not clear whether patients with Good syndrome exhibit as yet undiscovered specific genetic or immunologic abnormalities that clearly distinguish them from CVID.

Selective IgA Deficiency

There are two subclasses of human IgA: IgA1 and IgA2. They are encoded by separate genes on the heavy-chain C region locus on chromosome 14 (see Fig. 24-8). IgA1 predominates in serum (80% to 90%), whereas IgA1 and IgA2 are equally prevalent in secretions. Both subclasses are equally affected in selective IgA deficiency (SIGAD). SIGAD is defined as a serum IgA level of less than 0.07 g/L with normal serum IgG and IgM in a child older than 4 years of age in whom other causes of hypogammaglobulinemia have been excluded.[4] Note that this definition is restricted to the absence of serum IgA. There is no known clinical association with IgA levels between the lower limit of detection and the lower limit of the normal range. It is not appropriate to refer to patients with these nonzero low IgA values as being IgA-deficient.

SIGAD is seen in approximately 1 in 700 Caucasians in the United States.[407] In contrast, its incidence among Japanese is only 1 in 18,500. This presumably reflects population genetic differences, possibly related to the HLA complex. SIGAD has been associated with extended HLA haplotypes similar to those observed in CVID.[408,409] The majority of individuals with SIGAD are completely asymptomatic. Some may have a clinical course similar to that seen in CVID or in IgG subclass deficiency (discussed later). The proportion of patients with SIGAD is increased in a population of people with chronic lung disease, and 20 years' observation of blood donors with SIGAD has documented an increased incidence of respiratory infections and autoimmune disease.[410-413]

The spectrum of autoimmune syndromes associated with SIGAD is similar to CVID.[410-413] In addition, atopic diseases appear to be more prevalent among those with SIGAD, and some have also noted an increased incidence of the type of malignancies encountered in CVID. In rare cases, SIGAD has evolved into CVID, or levels of IgA have increased over time.[414,415] Treatment of SIGAD has generally focused on management of complications as they occur. In some instances, gamma globulin infusions may be helpful, especially if an associated IgG subclass or specific antibody deficiency is present (discussed later). However, researchers in one study did not find an association between a history of infections and lower antibody responses to pneumococcal polysaccharides.[411] Some studies do show an association of increased infections if there is an IgG subclass deficiency or mannose-binding lectin (MBL) deficiency together with SIGAD.[416]

Apart from the absence of IgA itself and its occasional association with abnormalities of IgG subclasses, there are few other characteristic immunologic abnormalities. Some researchers have found low levels of switched memory B cells in some patients and observed correlations with disease severity and autoimmune complications similar to those in CVID.[417]

Molecular genetic defects have not been described in SIGAD. Lesions in IgA C region genes are not found, except in rare instances associated with other deletions (discussed later). SIGAD and CVID have been associated with the HLA haplotype A1, B8, DR3 in Caucasians.[409,418] A SIGAD susceptibility locus (IGAD1) has been mapped to the boundary region between HLA class II and class III.[419,420] A more detailed analysis identified a positive association of SIGAD with HLA-DRB1*0301, DQB1*02 and a negative association with DRB1*1501, DQB1*0602. Another study identified an association of SIGAD with DRB1*0102, DQB1*0501.[421] The significance of these associations requires clarification.

SIGAD may occur as a drug side effect and has been reported with phenytoin, carbamazepine, valproic acid, zonisamide, sulfasalazine, gold, penicillamine, hydroxychloroquine, and nonsteroidal antiinflammatory drugs.[418] The IgA level may normalize after cessation of the drug.

Immunoglobulin G Subclass Deficiency

Four subclasses of IgG exist in humans: IgG1, IgG2, IgG3, and IgG4. Their designations order their prevalence in serum, with each constituting roughly 67%, 23%, 7%, and 3% of the total, respectively. A different gene encodes the heavy-chain constant region of each subclass (see Fig. 24-8). Each subclass has unique structural properties and plays a different role in immune responses as a result of different interactions with the complement system and with receptors for IgG on phagocytic cells and lymphocytes. In addition, IgG subclasses are produced in different relative amounts depending on the antigenic stimulus.[422] Mainly IgG1 is produced in response to soluble protein antigens. Viral antigens also elicit predominantly IgG1 responses and often significant amounts of IgG3 as well. Particular viruses (e.g., hepatitis, herpes simplex, and varicella) also elicit IgG4. The pneumococcal capsular polysaccharide response is almost exclusively of the IgG2 subclass, whereas *H. influenzae* type B (HIB) polysaccharide elicits mainly IgG2, with some IgG1 (the latter is found in younger children particularly). Note that the current HIB and pneumococcal (Prevnar) vaccines are protein conjugates and elicit responses characteristic of protein antigens.

IgG subclass deficiency (IGGSD) is defined as a level of one or more IgG subclasses greater than 2 SD below the age-adjusted mean with a normal total level of IgG. Precise criteria for diagnosis are difficult to establish because of variability in Ig measurements by various techniques (e.g., nephelometry and radial immunodiffusion) and the wide variability in normal ranges with respect to age and ethnicity. The significance of decreased levels of IgG subclasses in patients with recurrent infections is further clouded by the fact that the majority of individuals with isolated subclass deficiencies are asymptomatic. These factors make the diagnosis of IGGSD controversial.[423]

Patients with IGGSD commonly present with recurrent sinopulmonary infections of varying severity caused by common respiratory bacterial pathogens.[424-428] Some may also have recurrent diarrhea, often of infectious origin. Furthermore, atopic diseases such as asthma and allergic rhinitis are more prevalent in patients with IGGSD. Deficiency of the IgG2 subclass is detected most commonly in symptomatic patients. It may occur in isolation but is also usually associated with deficiency of IgG4, IgA, or both. Selective deficiency of IgG3 alone is likewise observed (most often in adult women) and is associated with the same clinical picture described earlier.[424,425] The lowest IgG4 levels are usually associated with IgG2 deficiency. Recurrent infections have been described in some patients with only IgG4 deficiency, although a diagnosis of isolated IgG4 deficiency is considered most controversial because normal ranges for IgG4 are poorly defined.

Several studies have shown an increased proportion of individuals with subclass deficiencies among patients with recurrent infections.[4] Not all of these patients have demonstrably impaired responses to vaccines, however. Thus the relationship between lack of an antibody isotype and susceptibility to infection is far from straightforward. Assessing the response to antigen challenge is an important element in the evaluation of these patients. Assessment of memory B-cell subsets may become a useful diagnostic tool for IGGSD; some studies suggest that reduced switched memory B cells have better a correlation with risk for infection than antibody responses do.[429]

The C region genes determining antibody classes and subclasses are arranged in the same transcriptional orientation on chromosome 14 (see Fig. 24-8). As with SIGAD, only rarely is clinically significant IGGSD associated with genetic lesions of IgG C region genes. This has been observed in a single reported patient with IgG2 deficiency, in whom mutation prevented expression of cell surface IgG2.[430] In fact, large deletions of Ig C region genes are surprisingly common; six multigene deletion haplotypes have been identified (see Fig. 24-8).[431] In one population with a high degree of consanguinity, individuals were found to be homozygous for one haplotype or heterozygous for two different haplotypes. Fifteen of 16 people with deletions on both chromosomes were entirely healthy despite a complete lack of one or more IgG subclasses or IgA1; one person had recurrent infections.[432] Similarly, two healthy siblings have been described, each having homozygous deletions of IgA1, IgG2, IgG4, and IgE.[433] Another group described a healthy 50-year-old man who had deletions encompassing the heavy-chain genes encoding IgG1, IgG2, IgG4, and IgA1.[434] This individual did not produce polysaccharide antibody but did produce IgG3 to protein antigens, including pneumococcal surface proteins. Finally, an analysis of the Ig heavy-chain loci of 33 patients with CVID revealed only two patients who were heterozygous for C gene deletions.[435]

Specific Antibody Deficiency with Normal Immunoglobulins

A population of patients with recurrent infections and poor antibody responses (mainly to polysaccharide antigens) have completely normal levels of antibody classes and subclasses. This condition has been called *specific antibody deficiency with normal immunoglobulins* (SADNI) or *functional antibody deficiency*.[436-438,439-441] In one retrospective compilation of 90 patients in a tertiary-care institution with newly diagnosed immunodeficiency, specific antibody deficiency with normal Igs was the most common diagnosis, made in 23% of patients.[442] Repeated immunization may lead to measurable antibody responses, although even protein conjugate pneumococcal polysaccharide vaccines may not be as effective as in healthy individuals.[440] Measurement of memory B-cell populations may correlate better with infection risk in these patients, although further study is required.[429] SIGAD, IGGSD, SADNI, and a subset of CVID may be entities in a spectrum with similar pathophysiologic characteristics. The natural history of IGGSD and specific antibody deficiency is usually slow spontaneous resolution.[415] Most children have a greatly reduced incidence of infections by late childhood.

Transient Hypogammaglobulinemia of Infancy

Transient hypogammaglobulinemia of infancy (THI) is, as its name suggests, an antibody deficiency beginning in infancy that resolves spontaneously, usually by 4 to 5 years of age.[443-447] It is defined as the occurrence of an IgG level more than 2 SD below the age-adjusted mean. Many patients also have low IgA, and some also have low IgM. Vaccine antibody responses are usually intact, but this is not always the case. Peripheral lymphoid tissue is sparsely populated with small or no germinal centers and markedly reduced plasma cell contents. Numbers of circulating B and T cells are generally normal, as are in vitro assays of lymphocyte function (e.g., mitogen response). One recent study documented higher B-cell counts than in an age-matched group.[448]

Ig levels in THI gradually increase over time, and the majority of patients have normal levels by the age of 4 or 5, rarely later.[443-447] Thus the diagnosis can be confirmed only after Ig levels normalize. Prospective studies show a preponderance of the diagnosis in male subjects and normalization of Ig levels at a median of approximately 2 years, with an upper limit of approximately 5 years. Female subjects and patients with lower IgG levels tend to take longer to normalize.

Immunoglobulin Class-switch Defects

As mentioned previously, naïve B cells express IgM and IgD on the cell surface. These different isotypes are generated by way of differential splicing of mRNA transcripts. When B cells are activated by antigen and interaction with helper T cells in germinal centers, they initiate a process of class-switching whereby the DNA intervening between the variable region gene and a downstream isotype is excised. In this manner, B cells begin to express IgG, IgA, or IgE. When this process is impeded, the amount of these isotypes produced is very low, while the amount of IgM may be normal or very high. These disorders are often referred to as *hyper-IgM syndromes*. However, there are many important differences among the disorders often placed in this group.[449]

X-Linked Immunodeficiency with Normal or Elevated IgM

As its name implies, X-linked immunodeficiency with normal or elevated IgM (XHIM, also HIM1) denotes a form of selective hypogammaglobulinemia G and A, together with normal or elevated amounts of IgM.[450-454,455] These patients are seen in the first 1 or 2 years of life with the recurrent sinopulmonary bacterial infections often found in those with hypogammaglobulinemia, together with opportunistic infections by organisms such as *P. jiroveci*, *Cryptosporidium*, and *Histoplasma*. Affected patients are also prone to the development of neutropenia, anemia secondary to parvovirus, stomatitis, sclerosing cholangitis, and liver and hematologic malignancies. A variety of autoimmune manifestations may be seen, including cytopenias, arthropathy, and inflammatory bowel disease.[456]

The number of circulating B cells is normal, but they express IgM exclusively (in association with IgD) on their surface. Immune responses are varied. Isohemagglutinins are often present, and vaccination may elicit specific IgM responses. No other isotypes are produced; there is no B-cell memory. Secondary lymphoid tissues are sparsely populated and do not contain germinal centers. In spite of the important defects in T-cell function for B-cell help, screening studies such as flow cytometric measurement of T-cell populations or in vitro proliferation tests are often normal.[450-455]

The genetic lesion in XHIM is in *TNFSF5* (tumor necrosis factor superfamily member 5), also known as CD40 ligand (CD40L) or CD154. [450-455] This is an integral membrane protein that is mainly expressed on T cells after an activating stimulus, such as interaction of the TCR with an MHC-peptide complex on the surface of a B cell or APC (Fig. 24-9). The signal delivered by T-cell CD40L to CD40 is critical for Ig class switching, the development of B-cell memory, affinity maturation of the antibody response (somatic hypermutation of Ig V regions), and the expression of important costimulatory molecules such as those of the B7 family by B cells and APCs (see Fig. 24-9).

The CD40 system has additional roles in the interaction of T cells with monocytes. Several T-cell–derived cytokines (granulocyte-macrophage colony-stimulating factor, IL-3, and IFN-γ) induce the expression of CD40 on monocytes. Furthermore, engagement of monocyte CD40 induces cytokine synthesis and activates tumoricidal mechanisms. These phenomena suggest an important interaction, the lack of which may underlie the predisposition to opportunistic infection and malignancy seen in patients with CD40 ligand deficiency.

Perhaps not too surprisingly, a clinically and immunologically identical immunodeficiency syndrome arises from mutations in the gene *TNFRSF5*, which encodes CD40.[451,454,457,458] Only a few patients with this defect have been found so far.

These defects in CD40L and CD40 (*TNFSF5* and *TNFRSF5*) are discussed here together with the humoral immunodeficiencies because of the prominence of the class-switch defect in the clinical expression. However, they are truly combined immunodeficiencies with important defects of T-cell function. In addition to IgG therapy and infection prophylaxis, these patients are candidates for HSCT.

Mutations in Activation-Induced Cytidine Deaminase and Uracil Nucleoside Glycosylase

Activation-induced cytidine deaminase (AID) and uracil nucleoside glycosylase (UNG) defects exclusively affect B-cell function while T-cell number and function are completely normal. They were originally defined in the medical literature as forms of hyper-IgM (HIM) syndrome, which leads to some confusion insofar as other forms of HIM are combined immunodeficiencies with important T-cell dysfunction (discussed previously). AID deficiency has been called HIM2[454,459-461] and UNG deficiency has been called HIM5[454,462] (see Table 24-8). The AID and UNG enzymes are RNA modifiers expressed in B cells that act during class-switch recombination. In the

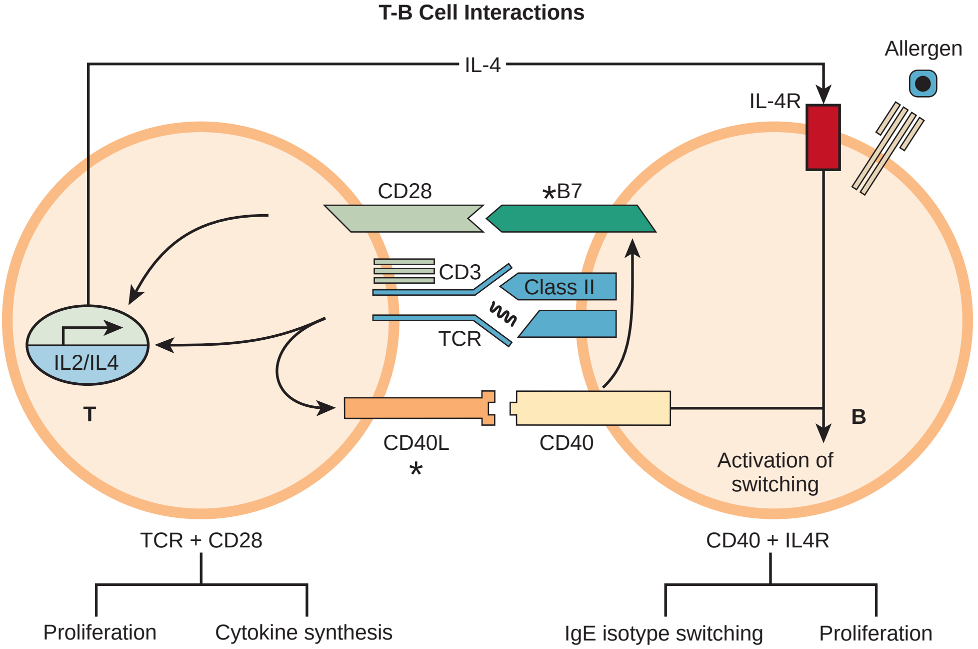

Figure 24-9 Signals required for T-cell activation by antigen-presenting cells (APCs), B-cell activation by the T cell, and B-cell immunoglobulin class-switching. The T-cell receptor (TCR) interacts with MHC + peptide. Subsequent to this interaction, the T cell expresses CD40 ligand (CD40L) and begins producing IL-2 and IL-4. CD40L interacts with CD40 on the APC (or B cell) inducing expression of B7-1 (also called CD80) and B7-2 (CD86). This interaction leads to full activation of APC function, macrophage killing capacity, or B-cell activation, depending on the cells involved. Binding of B7 molecules to CD28 on the T-cell surface provides an important costimulatory signal leading to full T-cell activation and increased cytokine production. IL-4 produced by the T cell interacts with its receptor on B cells to induce class-switching. Other cytokines act on other cell types to modulate their activities in the immune response.

absence of their activity, B cells cannot switch from production of IgM and IgD to production of downstream Ig isotypes (see Fig. 24-8). Somatic hypermutation is also affected. These processes normally occur during B-cell activation in germinal centers.

Another form of HIM syndrome with an unknown gene defect leads to impaired Ig class-switching recombination.[463-466] This has been called HIM4. All these disorders are very similar clinically and immunologically. Patients suffer mainly from respiratory tract bacterial infections and lymphadenopathy, and cellular immunodeficiency is not seen. IgG, IgA, and IgE levels are all low or absent; IgM levels tend to be higher than in the X-linked HIM syndrome. Patients tend to do well with IgG replacement.

Management of Humoral Immunodeficiency

Diagnostic Approach

Patients with recurrent infections, regardless of antibody class or subclass levels, should undergo thorough evaluation to rule out other potential predisposing factors (e.g., anatomic defects or environmental allergies).[4] The amounts of one or more antibody isotypes are reduced in many of these diseases.[3,4] The severity of the phenotype often correlates with the degree of hypogammaglobulinemia. The predisposition that patients have to particular types of infections may also depend on the affected isotypes (discussed later). It is always of the utmost importance to use age-adjusted reference ranges. Ig levels are low in infancy and rise throughout childhood. Most isotypes reach fully adult levels between the ages of 5 and 10 years.

Antibody titers to specific antigens may be measured before or after immunization (often both). The specific antibodies most commonly assayed for protein antigens are tetanus and diphtheria toxoids. With respect to polysaccharide antigens, measurement of antibodies to pneumococcal serotypes is frequently undertaken. If a child has had a particular illness (e.g., varicella), a specific viral antibody titer may be useful. Note that the HIB vaccines and newer pneumococcal vaccines (e.g., Prevnar-13) currently in use for primary immunization in children are protein conjugates. Thus measuring a polyribosylribitol phosphate or pneumococcal serum antibody concentration in children who have received these vaccines does not necessarily reflect a "pure" polysaccharide antibody response. The adequacy of carbohydrate responses may be tested by challenge with 24-valent pneumococcal polysaccharide vaccines (e.g., Pneumovax).[438,439,467-469] This vaccine produces reliable results in normal children as young as 1 year.[470] An unconjugated meningococcal vaccine (Menomune) may also be used to assess ability to respond to polysaccharides. In children who are not fully immunized or who are too young to immunize, isohemagglutinins may be measured as an indicator of the ability to generate polysaccharide antibody.[4]

Most children have been immunized with tetanus toxoid, HIB, and Prevnar, and antibody titers may be determined at the first visit. If titers are low, response to booster immunization may be assessed.

A high index of suspicion for antibody deficiency should be maintained in patients with recurrent, refractory, or severe infections. One study of primary antibody deficiency in the United Kingdom found that the median delay in diagnosis after the onset of symptoms (infections) was 2 years (mean, 4.4 years), even after the introduction of a set of national guidelines intended to reduce this delay.[471]

IgG Replacement Therapy

The mainstay of therapy for significantly impaired ability to produce antibody is IgG replacement.[4,472] As mentioned earlier, this therapy is also important for the treatment of any combined immunodeficiency in which defective antibody production may occur. Patients with XLA were the first to receive human gamma globulin therapy. The effect of intramuscular injections of gamma globulin was prompt and dramatic, with a reduction in the occurrence of infections. With the advent of preparations suitable for intravenous administration in the 1970s, this became the most common route of administration worldwide. A retrospective study of bacterial infections in patients with XLA showed a reduction in incidence from 0.4 to 0.06 per patient per year with IVIG therapy.[473] At present, administration of IVIG provides these patients with an almost normal lifestyle.[474-479] Many immunologists also apply chronic antibiotic prophylaxis in addition to IgG for patients with XLA, but this practice is not universal. All patients with CVID and with class-switch defects should also be treated with IgG infusions.[4,472,474,477,480-483] For these patients, as with XLA, many immunologists also apply chronic antibiotic prophylaxis.

In most countries gamma globulin replacement is administered predominantly by the intravenous route every 3 to 4 weeks. However, IgG can also be administered by subcutaneous infusion.[477,480,481,484] Smaller subcutaneous doses are given weekly or twice weekly or even daily. Intravenous infusion is generally well tolerated but requires intravenous access and is associated with frequent mild (10% to 20% of patients) or moderate (5%) side effects. Subcutaneous infusions may be administered by patients themselves at their own convenience with a much lower rate of systemic effects at the cost of generally mild and transient (24-hour) local irritation. The general efficacy of intravenous versus subcutaneous administration appears to be equivalent. Subcutaneous infusion is becoming increasingly popular.

Antibiotic Prophylaxis

For milder forms of antibody deficiency such as SIGAD, IGGSD, SADNI and THI, antibiotic prophylaxis is the more common first-line approach for infection prophylaxis.[4] However, regimens are not standardized. Commonly used agents include amoxicillin and trimethoprim-sulfamethoxazole. Depending on specific circumstances, other antibiotics may be chosen, such as clarithromycin or azithromycin, amoxicillin-clavulanate, or doxycycline. Also depending on circumstances, therapeutic dose or half-dose regimens may be applied. For any of these disorders (with the possible exception of SIGAD), IgG therapy may ultimately be prescribed if the response to antibiotic prophylaxis is poor, or if intolerable side effects or hypersensitivity precludes their continued use.[424,426,477,485,486] In these circumstances, there is usually a clearly observable reduction in the frequency of infections. IgG replacement for SIGAD is especially controversial because experience has not demonstrated consistent benefit.

General Care

Patients with antibody deficiency require regular monitoring for occurrence or progression of complications and adequacy of therapy.[4] Lung function should be measured regularly along with periodic assessment of hematologic parameters, liver and kidney function, and Ig levels. Therapy for autoimmune inflammatory complications in CVID and other antibody deficiencies generally follows regimens applied in similar situations in the absence of the immunodeficiency.[365,369,371,392,480] However, patients with primary immunodeficiency who are treated with immunosuppression for autoimmune or lymphoproliferative disorders may be more susceptible to infectious complications.

COMPLEMENT DEFICIENCIES

The complement system is composed of some 20 serum proteins, 5 complement receptors with varied distribution among leukocytes, and several integral membrane regulators found on most cells of the body.[487,488] The latter group of molecules limit cell damage as a result of a low constitutive level of complement activation. There are three distinct modes of complement activation: the classical pathway, the alternative pathway, and the lectin pathway. These pathways are shown in Figure 24-10. Soluble or surface-bound antigen-antibody complexes initiate the classical pathway; the alternative pathway is activated when complexes of C3b, factor B, and properdin are deposited on bacterial surfaces or extracellular matrix components. The lectin pathway is initiated by binding of MBL to mannose-containing microbial polysaccharides. The activation of the complement system by way of any of these pathways consists of sequential proteolytic interactions having a common outcome: cleavage (activation) of the C3 complement component to yield the anaphylatoxin C3a and the C3b fragment. C3b attaches to cell membranes (e.g., bacteria) and is the principal opsonin for phagocytosis. After cleavage of the C5 component (yielding the anaphylatoxin C5a), additional reactions are nonenzymatic aggregation of C5b, C6, C7, C8, and C9 to form the macromolecular membrane attack complex (MAC). The MAC is an amphiphilic cylinder; its hydrophobic end inserts into target cell membranes and permits free flow of ions and other solutes, which leads to metabolic derangement or lysis.[489] Genetic defects of almost all complement components are known. The clinical manifestations of these defects are categorized in Table 24-9. Complement deficiencies are among the rarest of primary immunodeficiencies, accounting for fewer than 1% of all patients diagnosed.

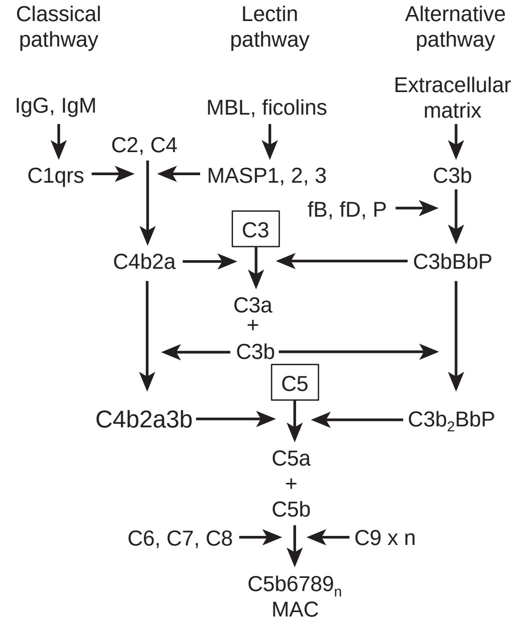

Figure 24-10 Complement activation pathways. The alternative pathway is initiated when the C3b fragment with factor B (fB) and properdin (P) bind to the extracellular matrix or some microbial polysaccharides. Factor D (fD) cleaves fB to yield the C3 convertase BbC3b. Addition of C3b creates the C5 convertase BbC3b2. The classical pathway begins when IgG or IgM bound to a surface forms a complex with C1qrs. The lectin pathway is initiated when mannose-binding lectin (MBL) or other initiators such as the ficolins and MBL-associated serine protease 2 (MASP2) bind to microbial polysaccharides. Activated C1qrs and MBL/MASP2 are both capable of cleaving C2 and C4 to yield the C3 convertase C4b2a. Addition of C3b to this complex yields the C5 convertase C4b2a3b. The C5 convertases generate C5b, the nucleus for the membrane attack complex (MAC), which is formed by the addition of one each of C6, C7, and C8 and several molecules of C9.

TABLE 24-9 Clinical Associations with Complement Deficiencies

Component	Symptoms/Syndrome Associated with Deficiency
C1q, C1r	Systemic lupus erythematosus–like syndrome
C2	Systemic lupus erythematosus–like syndrome, vasculitis, polymyositis
C4	Systemic lupus erythematosus–like syndrome
C3	Recurrent pyogenic infections
C5, C6, C7, C8, C9	Neisserial infection, systemic lupus erythematosus–like syndrome
C1-INH	Hereditary angioedema
Factor I, Factor H	Recurrent pyogenic infections, atypical hemolytic uremic syndrome
Factor D, Properdin	Neisserial infections
MBL, MASP-2	Recurrent pyogenic infections
Ficolin 3	Atopy (possibly also infection)

Deficiency of Classical Complement Pathway Components

C1 Deficiency

C1 is a large complex multimer consisting of three major subunits: C1q, C1r, and C1s. C1q is itself a complex of 18 separate polypeptides, 6 molecules each of C1qA, C1qB, and C1qC. The C1 complex is completed by the addition of two molecules each of C1r and C1s, which brings the total to 22 polypeptides. Patients with defects in any of the major subunits of C1 have a syndrome resembling systemic lupus erythematosus (SLE) and susceptibility to recurrent infections.[490-493] Deficiency of C1q may be caused by antigenically normal nonfunctional protein or complete absence of C1q. The *C1QA, C1QB,* and *C1QC* genes are closely linked on chromosome 1; defects in the *C1QB* and *C1QC* genes have been described. The genes encoding C1r and C1s are closely linked on chromosome 12, and mutations of both C1r and C1s have also been described. In addition to genetically determined or primary C1q deficiency, autoantibody-mediated depletion of C1q has been associated with SLE.[494-497]

C2 Deficiency

The monomeric C2 component of complement is the substrate for the activated C1s component of the C1q complex. Two fragments are generated in this reaction: The C2a fragment associates with C4b on a cell surface and becomes an activator for C3 (“C3 convertase”); the C2b fragment is a substrate for plasmin and releases a vasoactive peptide that may play a role in hereditary angioedema (HAE, discussed later). Approximately 50% of individuals with C2 deficiency are asymptomatic. The rest have one or more of the following: various forms of vasculitis such as discoid lupus erythematosus or SLE, chronic Henoch-Schönlein purpura, polymyositis, or recurrent pyogenic infections.[498-501] Only approximately 25% of C2-deficient patients are prone to infections. C2 deficiency is associated with low levels of IgG subclasses, and low levels of IgG4 and IgA may play a role in determining susceptibility to infection.

The gene encoding C2 resides in the class III region of the HLA complex on chromosome 6. Between 1% and 1.5% of Caucasians are heterozygous for a null *C2* allele (*C2Q0*). Thus approximately 1 in 10,000 will be homozygous for *C2Q0* and have a complete deficiency of C2.[498-501] Two forms of C2 deficiency independent of *C2Q0* have been identified. In type I, a mutation results in loss of a mRNA splice site and C2 cannot be translated. In type 2 deficiency C2 is not secreted, but the basis for this is unknown.

C4 Deficiency

The C4 component is another substrate for activated C1s. The C4a fragment is a very weak anaphylatoxin, and the C4b fragment associates with C2a on a cell membrane to constitute C3 convertase. Complete deficiency of C4 is rare. Virtually all such individuals with C4 deficiency have SLE and severe glomerulonephritis.[502-506] Renal failure and infection are the leading causes of death. The genes encoding C4 are also located in the class III region of the HLA complex. There are two copies on each chromosome, *C4A* and *C4B*. Each encodes proteins that differ in structure only minimally, although their biologic activities are distinct. Null alleles at these loci occur frequently; 35% of people have one copy of either *C4AQ0* or *C4BQ0*. Ten percent of the population have two null alleles, and 1% have three. The presence of four null alleles (complete C4 deficiency) is rare. All of these partial deficiency states are often asymptomatic. One study has found an association of *C4B* null alleles with Henoch-Schönlein purpura.[507] Older studies have found HLA haplotypes containing C4 null alleles frequently in patients with SLE.[508] However, more recent studies suggest that this association arises by linkage disequilibrium of C4 with the MHC locus rather than by the C4 genes themselves.[509] The relatively high rate of occurrence of C2 and C4 null alleles leads to combined heterozygous partial deficiencies of both in about 1 in 1000 Caucasians. Approximately one third of these patients have SLE and other autoimmune diseases.[510] It is possible that this association also may be the result of linkage disequilibrium with MHC.

C3 Deficiency

The C3 component sits at the confluence of all three pathways of complement activation. The various fragments of C3 generated through the action of C3 convertases (C4b2a and C3b2Bb), as well as other serum proteases, have diverse influences within the immune system. C3a is a potent anaphylatoxin, whereas C3b is the principal opsonin for phagocytosis and is a component of enzyme complexes in the alternative pathway of complement activation. Additional C3 fragments influence lymphocyte function. For example, C3d is an important regulator of B-cell activation.[511] Patients with C3 deficiency are susceptible to recurrent pyogenic infections affecting any organ system, and this condition is often clinically indistinguishable from hypogammaglobulinemia. These patients also may exhibit skin, kidney, and joint inflammation caused by immune complex deposition as well as a variety of autoimmune diseases.[512-514]

Deficiency of Alternative Complement Pathway Components

Properdin Deficiency

Properdin stabilizes the alternative pathway C3 convertase. The properdin gene is located on the X chromosome. Lack of properdin does not cause any changes in serum levels of complement components; activation through the alternative pathway is inefficient. Susceptibility to respiratory bacterial infections, *Neisseria* infections, and SLE has been associated with properdin deficiency.[510,515-518]

Factor D Deficiency

Factor D cleaves factor B after it associates with C3b. Factor D deficiency is associated with recurrent respiratory bacterial infections, pneumococcal sepsis, *Neisseria* infections, and glomerulonephritis.[519-522]

Deficiency of Lectin Pathway Complement Components

Mannose-Binding Lectin Deficiency

MBL is a member of the collectin protein family, which also includes lung surfactant proteins A and D.[523] MBL has a structure similar to C1q and interacts with polysaccharides containing mannose, glucose, and fucose, as well as acetylated derivatives of these sugars. Thus MBL may interact with members of virtually all classes of infectious microbes. Three proteins called MBL-associated serine proteases (MASPs) 1 to 3 are similar to C1r and C1s. MASP-2 may have the most important role in catalyzing cleavage of C2 and C4 in a manner analogous to C1s. Once this is accomplished, the classical pathway C3 convertase has been created and further reactions are identical to the classical pathway. There are polymorphisms of the gene encoding MBL that affect both structure and expression. Structural polymorphisms may impair the ability of MBL to form functional oligomers that bind effectively to carbohydrates and may also impair the association with MASP-2 and subsequent activation of the remainder of the classical pathway. Promoter polymorphisms lead to variation in blood MBL levels of greater than 1000-fold from 5 ng up to 10 μg/mL. A clinically relevant lower limit is not well established. Many studies use values of approximately 100 to 200 ng/mL, although slightly different values are occasionally used. MBL levels also vary among ethnic groups. The genotype or functional tests may be more informative than the serum level alone because it is possible to have normal serum levels of a nonfunctional protein.

The clinical significance of MBL measurement is controversial. Low blood MBL level or function does not by itself clearly predispose to disease, except possibly during infancy, when it may be associated with a higher rate of bacterial respiratory tract infections.[523] One study suggests that the (possible) increased susceptibility to pneumococcal infections in MBL deficiency may be serotype specific.[524] In other words, MBL-determined host defense is more important for some serotypes than for others. A variety of other types of conditions have been reported to be associated with MBL-deficiency, including pertussis,[525] cryptococcal meningitis,[526] cryptosporidiosis,[527] recurrent vulvovaginal candidiasis,[528] and the occurrence of septic shock in pyelonephritis as a result of *E. coli*[529] or severe course and fatality in adults with community-acquired pneumonia.[530]

Some reports also suggest that in the setting of other disease processes or stresses on the immune system, MBL deficiency predisposes to a higher rate of a variety of infectious complications. For example, one study reported a higher rate of invasive aspergillosis in MBL-deficient patients with secondary immune compromise resulting from acquired immunodeficiency virus or treatment with steroids or cancer chemotherapy.[531] Another report found a higher rate of bacterial infections in patients with low MBL and hepatic cirrhosis[532] or patients who underwent liver transplantation[533] or HSCT.[534] Another group reported a higher rate of CMV reactivation in MBL-deficient patients after lung transplantation.[535] Interestingly, overall survival was superior in those with low MBL in this study. Similarly, low blood MBL levels may also increase the severity of primary immunodeficiency, such as in CVID or with IgA/IgG subclass deficiencies or properdin deficiency.[416,536-538]

MBL levels may also impact certain inflammatory states. A low level of MBL has been associated with a lower rate of acute rejection after heart transplantation[539] and smaller infarct size and better outcome after cerebral infarction.[540] However, another study reported a higher risk for myocardial infarction in adults with MBL deficiency.[541] MBL deficiency has also been reported to predispose to or worsen autoimmune or inflammatory diseases such as rheumatoid arthritis, SLE, and celiac disease.[542]

There are also examples of studies reporting negative findings regarding disease susceptibility and MBL levels. For example, a recent study in 105 HIV patients did not find a significant association between low MBL levels and the occurrence of infection.[543] Another study did not find correlation of MBL levels with outcomes in cystic fibrosis patients[544] (whereas earlier studies had reached opposite conclusions[544-548]). The situation may be even more complex because of discrepancies between studies based on measuring MBL levels versus those based on genetics. For example, MBL genotypes generally thought to be predictive of serum level and function did not correlate with infection rates in patients with colorectal cancer, in contrast to a prior study that had found significant associations with the serum levels of MBL.[549]

In spite of the controversy surrounding the clinical significance of MBL levels, recombinant human MBL is under development as a therapeutic agent; one phase I trial has shown no adverse effects of administration to healthy MBL-deficient individuals.[550]

The ficolins 1-3 are also members of the collectin family of molecules and can interact with MASPs 1 to 3 and initiate the lectin pathway of complement activation. Deficiency of ficolin 2 (also called L-ficolin) has recently been associated with recurrent respiratory infections and atopy in children.[551] However, a more recent report from the same group suggests that the main clinical association of low ficolin levels is with atopy rather than with infection.[552] The significance of these findings requires clarification.

MASP-2 Deficiency

Abrogation of MASP-2 function is expected to have the same consequence as the absence of MBL function: failure to activate complement by way of the lectin pathway. Patients homozygous for *MASP2* mutations have been reported to have similar clinical associations as described for MBL deficiency.[524,530,549,553-555] All of the controversy regarding the clinical importance of MBL levels and genetics applies equally to a discussion of functional MASP2 polymorphisms or mutations.

Deficiency of Terminal Complement Components

Recurrent neisserial and pneumococcal infections and rheumatic disease have been reported in patients with C5,[556,557] C6,[558,559] and C7[560] deficiencies. C6 deficiency has been found in approximately 1 in 1600 African-Americans in the southeastern United States in association with a higher incidence of meningococcal meningitis.[561]

The C8 molecule is a heterotrimer of chains designated α, β, and γ. The *C8A* and *C8B* genes are on chromosome 1, whereas the *C8G* gene resides on chromosome 9. C8 deficiency is also associated with recurrent neisserial infection; patients have been identified with lesions of *C8A* or *C8B*.[562-565] Patients with lesions in the *C8A* genes also lack C8 γ protein, even though the latter genes are normal, because C8 α and γ are normally covalently linked. C9 deficiency is usually asymptomatic[566]; a few patients with recurrent neisserial infections have been described.[567,568] One patient with IgA nephropathy associated with C9 deficiency has been reported.[569] C9 deficiency has also been found in one patient with dermatomyositis.[570] Allotypy at IgG Fc receptor gene loci may have an impact on the susceptibility to infection in patients with deficiencies of terminal complement components.[571]

Deficiency of Complement Regulatory Factors

C1 Inhibitor Deficiency (Hereditary Angioedema)

HAE exhibits autosomal dominant inheritance. The symptoms of this disease are unpredictable recurrences of acute and profound subepithelial edema in a variety of anatomic locations.[572,573] Physical trauma may be a precipitating factor. The distal ends of the extremities, face, intestines, and pharynx are often affected. Extremity edema is painless but impedes function. Intestinal edema causes excruciating pain and is associated with abdominal distention, vomiting, and diarrhea. Pharyngeal edema may lead to fatal airway obstruction.[574] Attacks evolve over a period of approximately 12 hours and resolve in 24 to 48 hours. Attacks in childhood are not uncommon but occur less frequently than in adulthood. An increase in incidence and severity often occurs during puberty and is sustained thereafter. Attacks may be associated with menses in females. Patients may become symptomatic or may have more frequent symptoms when receiving estrogen replacement or contraceptive therapy.

C1 esterase inhibitor (C1-INH) is a serum serine protease inhibitor (Serpin G1) that limits activities of the complement proteases C1r and C1s, as well as those of kallikrein, coagulation factors XIa and XIIa, and plasmin.[572,573] In type I HAE (≈85% of patients), levels of C1-INH are less than 30% of normal. Patients with type II HAE have normal levels of a mutated (nonfunctional) protein. There is at least one additional form of HAE with autosomal dominant inheritance and completely normal C1-INH function. It is designated HAE type III and arises from mutations in the gene encoding coagulation factor XII.[575] The mechanism of angioedema is not known. In HAE I and II the unopposed activities of C1r, C1s, and kallikrein lead to consumption of C2, C4, and kininogen.[572,573] Diminished levels of these proteins are highly characteristic of HAE. Peptides derived from C2 and especially bradykinin cause the increase in vascular permeability and edema.

The *SERPING1* gene is located on chromosome 11. A variety of genetic lesions have been identified in patients with HAE.[575] Despite having one normal copy of the gene, patients have inadequate levels of C1-INH, well below the 50% one would expect to be due to a simple gene dosage effect. The mechanism that leads to inhibition of transcription of the normal gene is unknown. Although inheritance is autosomal dominant, as many as 10% to 25% of patients may express new mutations.

Acquired forms of HAE have also been described. In acquired angioedema (AAE) type 1, C1-INH levels decrease by an unknown mechanism, usually as a paraneoplastic process associated with lymphoma and lymphoproliferative disorders.[576-581] In AAE type 2, autoantibodies against C1-INH deplete it from serum.[582-584] These antibodies may arise sporadically, in the context of other autoimmune syndromes, or in association with lymphoproliferation.

There are three distinct problems in the management of HAE or AAE. These are the control of acute attacks when they occur and the short-term (i.e., preprocedure) and long-term prophylaxis of acute attacks.[585,586-588] For management of acute attacks in patients with HAE, medications such as epinephrine, antihistamines, and corticosteroids, used to treat angioedema subsequent to hypersensitivity reactions, are entirely useless because the mechanism of swelling in HAE is unrelated. Analgesia is indicated for painful abdominal crises. Airway protection is vital and may require a tracheostomy.

Recently, several new products have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of acute attacks of angioedema. These include the human plasma–derived purified C1 inhibitor Berinert,[589,590] a recombinant kallikrein inhibitor,[591-594] and a peptidomimetic bradykinin receptor 2 inhibitor.[595-597] All of these drugs have proved effective for the treatment of acute HAE attacks, reducing the intensity of angioedema and shortening the time to resolution. Other medications may be used if these are not available. Fresh frozen plasma has been used in attempts to replace C1-INH. There are several anecdotal reports of efficacy of this therapy.[598] However, this is not considered first-line therapy for acute attacks with the availability of newer agents. Tranexamic acid may also be effective, but this is also a second-line agent.[585-588]

Several strategies are available for short- and long-term prophylaxis of angioedema attacks. Short-term prophylaxis is indicated whenever a patient is to undergo a procedure (e.g., invasive dental work or surgery) that has the potential to precipitate an attack. Long-term prophylaxis is used to reduce the frequency of spontaneous attacks. Impeded androgens such as danazol, stanozolol, and oxandrolone are useful for short- and long-term prophylaxis.[585-588] These hormones act to increase expression of the normal *SERPING1* gene. Pediatric use is limited by the tendency of these hormones to promote epiphyseal closure; use in female subjects is limited by their undesirable virilizing effects. Tranexamic acid is also useful as long-term prophylaxis. Recently, another purified human plasma–derived C1 inhibitor product (Cinryze) has been FDA approved for prophylactic therapy.[599-601] Rituximab has been used with mixed success in a small cohort of patients with AAE resulting from autoantibodies to C1-INH.[602]

Factor I Deficiency

Also known as C3 inactivator, the disulfide-linked heterodimeric complement regulatory molecule factor I cleaves C3b. Deficiency of factor I leads to increased degradation of C3 (and factor B), principally because of the inability to control constitutive low-level activity of the alternative pathway of activation. These patients have manifestations of C3 deficiency such as recurrent infections, urticaria, and immune complex disease.[603-607] Factor I deficiency is also associated with atypical hemolytic uremic syndrome.

Factor H Deficiency

Factor H cooperates with factor I in the inactivation of C3b; its absence leads to reduced C3 and factor B and a syndrome of recurrent infections with *Neisseria meningitidis* and membranoproliferative glomerulonephritis.[608-614] Both familial and sporadic relapsing hemolytic-uremic syndromes have also been associated with mutations in factor H. Similar clinical complications result from autoantibody-mediated depletion of factor H.[615-617]

Diagnosis and Management of Complement Disorders

Clinical tests are available to assess the function of each of the three major pathways of complement activation.[4,487,488,516,618-620] The lectin pathway is not as frequently evaluated because the definition of clinically significant deficiency is controversial. Activation of the classical pathway is measured by the CH50 assay (total classical pathway hemolytic assay), which can be performed by a variety of methods. The alternative pathway is assessed by a similar test called the AH50. If the CH50 is low and the AH50 is normal, then there is likely to be a defect in C1, C2, or C4. If the AH50 is low and the CH50 is normal, there is likely to be a defect in properdin, or factor D. If both are low, it is likely that there is a defect in any of the terminal pathway components (C3-C9). Complement depletion caused by consumption in an inflammatory process will lead to depression of both CH50 and AH50. The same situation is seen in regulatory component defects (factor H and factor I) because of consumption of C3.

Antibiotic prophylaxis is the mainstay of long-term management of the infectious predisposition in complement deficiencies.[4,489,618] Patients should also maintain fully protective levels of antibodies for common encapsulated organisms such as HIB, pneumococcus, and meningococcus. The autoimmune or inflammatory complications are managed according to standard regimens as they arise. It should be noted that experience is limited with newer biologic therapies in the inflammatory states associated with complement deficiency. Eculizumab is an anti-C5 monoclonal antibody that inhibits the terminal pathway and is approved for the management of atypical hemolytic-uremic syndrome.[621]

Mucolipidosis Type II/ III (I-Cell Disease and Pseudo-Hurler Polydystrophy)
Lysosomal Acid Lipase Deficiencies
Neuronal Ceroid Lipofuscinoses
Krabbe Disease
Metachromatic Leukodystrophy

This chapter provides an overview of the lysosomal storage diseases (LSDs) with particular reference to their specific hematologically related manifestations or treatments. Comprehensive reviews, such as *Chapters in the Metabolic and Molecular Bases of Inherited Diseases,* 9th ed., are available for molecular genetics, biochemistry, enzymology, and phenotypes, and these sources should be consulted for details.

THE LYSOSOMAL SYSTEM

The lysosome is an intracellular organelle originally encompassing two concepts: (1) an intracellular acidic vacuole for digestion of intracellular and extracellular organic materials, and (2) biogenesis mechanisms to deliver or target its constitutive proteins, lipids, and other components.[1] Inherent in these were the foundations of the pathogenesis and therapy for the LSDs (i.e., the lysosomal accumulation of specific substrates for particular digestive hydrolases and the potential to correct such abnormalities by the reconstitution of the appropriate levels of enzyme activity in the lysosome). These concepts, although still relevant, evolved to include the lysosome as an integral part of a major intracellular system for the clearance of internal and external macromolecules and organelles (i.e., the autophagy system).[2,3] In addition, the lysosome can no longer be considered as a simple digestive vacuole but rather as a complex organelle functioning as a signal system that specifies its tissue or cellular compositions, modulates major metabolic processes (e.g., cholesterol and triglyceride synthesis),[4] and initiates inflammation. This complexity and its integration with the autophagy system preclude the LSDs as a simple result of inert intracellular accumulations of macromolecules and require their reconceptualization to complex disorders with wide ramifications within specific cellular types and throughout the body. Although the specific accumulated substrates may have differing effects on and manifestations in selected tissues, the disruptions of intracellular clearance through autophagy and of dysregulated metabolism are generally unifying, albeit heterogeneous, concepts for the LSDs. Indeed, the LSD disruptions of the lysosomal/autophagy/mitophagy system should be more properly termed *the lysosomal autophagy system diseases* (LASDs) (Fig. 25-1). *LSD* will be used here in its conventional sense, but the concept of widespread disruption of cellular processing is essential to the evolving view of these diseases.[5] These disruptions lead to heterogeneous effects, including macrophage activation and cytokine or chemokine storms (e.g., Gaucher and Niemann-Pick diseases), dysmorphology and skeletal malformations (e.g., mucopolysaccharidoses), and neuroinflammation and neuronal apoptosis or necroptosis (e.g., neuronopathic Gaucher disease, neuronal ceroid lipofuscinosis, and Krabbe diseases).

Morphology and Physiology

Lysosomes are membrane-bound, specialized organelles that normally constitute approximately 5% to 10% of the intracellular volume. Lysosomes are found in all

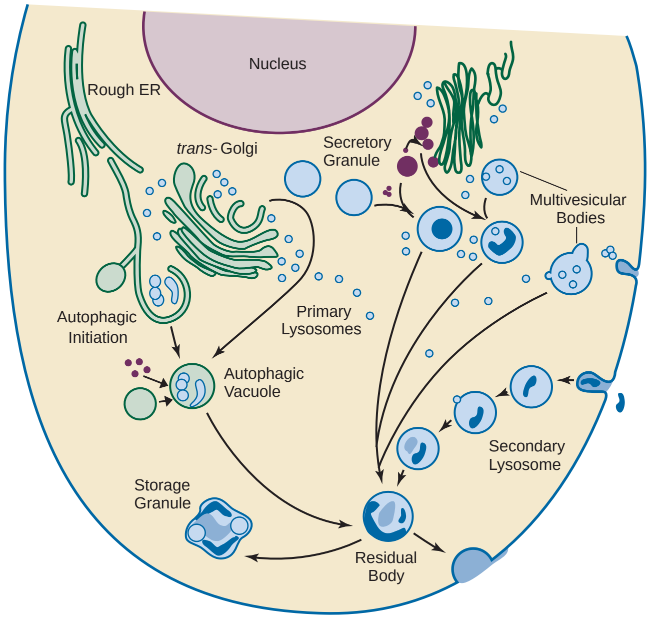

Figure 25-1 Schematic of the lysosomal/autophagy system. Primary lysosomes derive from the *trans*-Golgi as early endosomes and mature into late endosomes. These endosomes become increasingly acidic, which promotes dissociation of targeting signals from their receptors (e.g., M6P, with localization of the associated proteins to the primary lysosomes). The receptors are recycled to the Golgi and endoplasmic reticulum *(ER)* for reuse. The M6P receptor can also move to the plasma membrane for uptake of external proteins with that signal. Primary lysosomes also fuse with autophagic vacuoles for degradation of internal organelles (e.g., mitochondria) and extrusion from the cells as residual bodies. Multivesicular bodies (MBs) are formed by fusion of endosomes/secretory granules with invaginations from the plasma membranes. The internal vesicles of the MBs are inside-out plasma membranes. The MB fuse with lysosomes and provide surfaces for glycolipid degradation. In the lysosomal storage diseases, this complex machinery is disrupted by the increased physical size of the lysosomes and the biological, signaling, and toxic effects of the accumulated substrates.

nucleated cells but vary in size, morphology, and content with cell type. The characteristic azurophilic-staining granules in polymorphonuclear leukocytes and eosinophils are lysosomes. Moreover, lysosomes are abundant in cells of the macrophage/monocyte system.

Ultrastructure of the lysosome reveals a unit membrane surrounding polymorphic vacuoles, which fuse with pinocytic or phagocytic vesicles containing exogenous material (heterophagy) or with components of the autophagocytic system.[6] The undigested material remaining in secondary lysosomes becomes a residual body that can be extruded from the cell by way of an exocytosis pathway (e.g., into bile from the liver and into urine from the kidney).

Biosynthesis and Biogenesis

The lysosomal system represents the major site of intracellular compartmentalized degradation and potentially requires more than 200 different proteins for formation and modulation of its functions.[7,8] However, the protein composition of the lysosome varies considerably with the tissue or cell source. The expression of these proteins, and therefore lysosomal biogenesis, has been proposed to be controlled by the master regulator, *TFEB*, as are many of the autophagy proteins as part of the CLEAR system for intracellular degradation of macromolecules.[3] Lysosomes contain more than 70 hydrolytic enzymes, each with specificity to degrade selected proteins, glycoproteins, nucleic acids, polysaccharides, glycolipids, phospholipids, and neutral lipids. The lysosomal membrane contains many transmembrane- and membrane-associated proteins for maintenance of the acidic interior and its fusion capabilities.[7,9]

Most of the soluble lysosomal hydrolases are targeted to the lysosome by a direct route mediated by the mannose 6-phosphate receptor system.[8] In comparison, peptide sequences, rather than carbohydrate recognition markers, target most of the lysosomal transmembrane proteins indirectly, after transport to the plasma membrane and reinternalization with delivery to the lysosome.[7,10] The targeting mechanisms remain incompletely understood for several lysosomal membrane proteins, as are the roles of alternative targeting mechanisms (receptors) for some portions of soluble proteins.[8,10,11] Many soluble lysosomal enzymes are secreted from cells, and this process forms the basis of potential cross-correction of nearby cells.

All lysosomal proteins and enzymes are synthesized on the rough endoplasmic reticulum (ER) and gain access to the ER lumen by way of a leader, or signal, peptide (Fig. 25-2). The proteins are cotranslationally glycosylated on specific asparagines (*N*-linked glycosylation) as they enter the ER lumen.[12] Once glycosylated, vesicle-mediated transport delivers these proteins to the *cis*-Golgi. The oligosaccharide side chains are remodeled as they transit from the *cis*- to *trans*-Golgi and acquire specific sugars from Golgi glycosyltransferase that are resident in the *cis*, *mid*, and *trans*-Golgi.[13,14] For soluble lysosomal proteins a specific trafficking signal, mannose 6-phosphate (M6P), for lysosomal localization is added in the mid-Golgi.[8,15,16] The M6P-tagged proteins bind to the M6P receptor until they undergo an acidic pH-mediated dissociation in the late endosomes and are released into the lysosomal lumen. Small amounts of these soluble proteins are secreted from the cell and can be endocytosed by way of the M6P receptors on the plasma membrane for lysosomal delivery. This is the mechanic basis for metabolic cross-correction following hematopoietic stem cell transplantation (HSCT) in some LSDs. Membrane-bound lysosomal proteins use different receptors that recognize specific dileucine and other hydrophobic sequences for their delivery to the lysosomes.[10] The membrane-associated enzyme, acid β-glucosidase (glucocerebrosidase; i.e., the Gaucher disease enzyme) has a unique peptide sequence that binds to LIMP-2, lysosomal integral membrane protein 2, (Grabowski, unpublished), which is the specific receptor for this enzyme.[17] This enzyme and other membrane-bound lysosomal proteins do not normally secrete from cells and thus cannot cross-correct deficient cells.

Excellent recent reviews of lysosomal biogenesis, protein sorting, and molecular events of the dynamic lysosomal and autophagy systems are available, and the reader is referred to these for details.[2,18-22]

Figure 25-2 Overview of targeting mechanisms for lysosomal enzymes to the lysosome. Lysosomal enzyme precursors are synthesized on the rough endoplasmic reticulum (ER) with penetration into the ER lumen by way of a leader sequence. The enzymes are cotranslationally glycosylated and transported in vesicles to the *cis*-Golgi. During transit through the Golgi, the attached oligosaccharides are remodeled with subtractions and additions of specific sugars to form *N*-linked high mannose, complex, or hybrid oligosaccharide side chains. An important modification is the addition of M6P *(blue)*, which is the targeting signal for most soluble lysosomal proteins. The M6P receptor and M6P-modified proteins dissociate, owing to a drop in pH, in the late endosomes with release of the protein into the lysosomal lumen and regeneration of the endosome. The M6P receptor is recycled to either the mid-Golgi or the plasma membrane. Alternative mechanisms exist for integral or associated lysosomal membrane proteins. The red star is the LIMP2 receptor protein that transports acid β-glucosidase, the Gaucher disease enzyme, by way of a peptide sequence to the late endosome, where they dissociate by way of an acid-mediated mechanism. LIMP2 and other lysosomal integral membrane proteins are trafficked to the lysosome by dileucine or other hydrophobic motifs.

Pathogenesis

Hers[23] conceptualized the inborn lysosomal diseases in 1965 and proposed that excessive lysosomal accumulation of substrate leads to an increased number of lysosomes within cells, disruption of normal cell functions, and possibly cell death. In general, the signs and symptoms of each LSD primarily reflect the normal pattern of distribution of the enzymes' substrates.[24,25] In Gaucher disease type 1 (discussed later), turnover of senescent erythrocyte and leukocyte membranes containing glucosylceramide leads to its accumulation in the macrophage/monocyte system. Similarly, disorders of ganglioside metabolism involve principally the central nervous system (CNS) because gangliosides normally have higher turnover in this tissue. Compounds that are normally abundant in all tissues lead to generalized organ dysfunction (e.g., mucopolysaccharidoses and glycoproteinoses). Because of the disruptions of the lysosomal and autophagy system, secondary accumulations of various compounds do occur; the mechanisms for such accumulations are poorly understood.

OVERVIEW OF LYSOSOMAL STORAGE DISEASES AND THEIR DIAGNOSES

The LSDs are caused by deficiencies of a single or multiple lysosomal proteins. This underscores the lack of redundancy for these proteins and their importance in maintaining cell homeostasis. Most LSDs result from single enzyme or protein deficiencies resulting from mutations in their respective genes. The essential need for specific enzymes implies that if a single enzyme is deficient or functionally defective, the hydrolytic pathway is halted at the level of the missing enzyme, and its specific substrate (or substrates) accumulates in the lysosome with resultant organelle, cellular, and organ dysfunction. Some LSDs have multiple enzyme or protein deficiencies that result from mutations in single genes that are necessary for posttranslational processing or assembly or stability of a multiprotein complex. Examples include mucolipidosis II and III that disrupt the M6P targeting of many soluble lysosomal proteins to the lysosome, thereby leading to intracellular deficiencies of most soluble lysosomal enzymes.[26] Multiple lysosomal hydrolase defects also result from single gene defects that alter specialized posttranslational processing or multienzyme complex formation. Multiple sulfatase deficiency, in which all, not only lysosomal, cellular sulfatase activities are deficient, results from a single gene defect that encodes an active site modification enzyme that is essential for the activity of all sulfatases.[27,28,29] Multiprotein complex formation is defective in combined β-galactosidase/neuraminidase/"protector protein" deficiency in which there is a deficiency of a "protective protein (cathepsin A)" that is essential for the formation and stability of the tri-enzyme complex.[30]

All LSDs are inherited in an autosomal recessive manner, except for Fabry disease, Hunter syndrome (MPS II), and Danon disease, which are X-linked. Extensive allelic heterogeneity exists in all the LSDs, including many single base substitutions, premature chain terminations, and insertions and deletions of part or all of the respective genes. Some of the LSDs exhibit founder effects leading to a common mutation (or mutations) in specific demographic or ethnic groups. New alleles are regularly being discovered in all of the LSDs, and databases for many LSD mutations are maintained. Polymorphic variation also occurs in some of the alleles, and these can affect the resultant phenotype of a specific disease-causing genotype. Imperfect genotype-phenotype correlations exist, but in general this information can inform the anticipated prognosis and therapeutic options (discussed later).

Because many of the enzyme-defective LSDs are very rare, enzyme assays remain the gold standard for antenatal and postnatal diagnoses. Indeed, identification of a "mutation of unknown clinical significance," which often occurs in unrelated families with an LSD, requires enzyme confirmation of the diagnosis. For known pathogenic mutations in genes encoding enzymes and proteins in specific families or ethnic groups, molecular diagnosis is highly reliable, particularly for heterozygote detection and prenatal diagnosis.

For enzyme diagnosis, serum, plasma, or mixed leukocytes provide readily available sources, and reliable assays using synthetic fluorogenic or colorimetric substrates are available. LSD enzymes require different sources for assay; for example, serum and plasma or peripheral blood leukocytes are routinely used for many of the LSD-associated enzyme assays. Nucleated cells are needed for the diagnosis of Gaucher disease because the relevant enzyme is not secreted. Recently, dried blood spots have become more generally available for screening studies, but definitive enzyme assays should be used for confirmation. Antenatal diagnosis is available for most LSDs. Such sample needs are specified on the website *Gene Tests* (ncbi.nlm.nih.gov/sites/GeneTests/).

The Sphingolipidoses

The sphingolipidoses are characterized by defective or absent lysosomal hydrolysis and accumulations of specific sphingolipids in lysosomes. Mutations leading to either defective or deficient function of sphingolipid hydrolases or their specific activator proteins (also known as *saposins*) are the bases for these diseases. The shared structures of the sphingolipids include sphingosyl and fatty acyl acid chains that are covalently linked to form the ceramide. Attachment of various head groups to the ceramide backbone produce sphingomyelin, a phospholipid, and the more than 400 glycosphingolipids that contain single to multiple glycosyl residues. The glycosyl, fatty acid acyl chain, and sphingosyl components vary in structure with tissue, cellular, and subcellular localization. The sphingolipids are crucial structural elements of cell membranes and have important roles in cell signaling and recognition. Among the sphingolipidoses, Gaucher disease; Niemann-Pick disease types A, B, and C; Farber disease; GM_1 gangliosidosis; and GM_2 gangliosidosis have significant hematologic manifestations and effects.

Gaucher Disease

Gaucher disease, one of the more common LSDs, is an autosomal recessive trait resulting from more than 350 mutations at the *GBA1* locus and the resultant deficient or defective activity of the acid β–glucosidase (glucocerebrosidase).[31] Gaucher disease has a frequency of approximately 1/57,000 in the general population, and the type 1 variant has its greatest frequency in the Ashkenazi Jewish population, with a frequency of approximately 1/855.[32]

Decreased catalytic activity or instability of acid β–glucosidase leads to accumulation of glucocerebroside (glucosylceramide) and its deacylated analog, glucosylsphingosine, in the lysosomes of visceral cells of the monocyte lineage, termed Gaucher cells.[31] Gaucher cells (Fig. 25-3) accumulate in the liver, spleen, bone marrow, lung, and lymph nodes, leading to hepatomegaly, splenomegaly, anemia, thrombocytopenia, destructive bone disease, bone marrow infiltration, pulmonary disease, and lymphadenopathy.

Three clinical variants of Gaucher disease are classically described, depending on the absence or presence and severity of primary CNS involvement. Gaucher disease type 1, the "non-neuronopathic" variant, accounts for approximately 90% of all cases in European and North

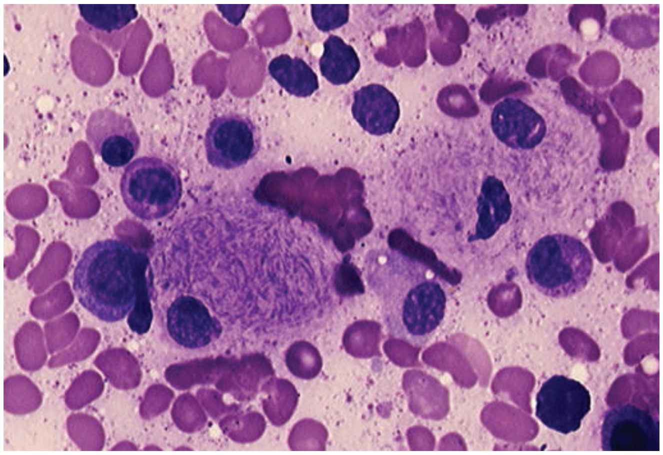

Figure 25-3 Bone marrow Gaucher cell: Light micrograph of bone marrow demonstrating characteristic enlarged, lipid-laden macrophages, "Gaucher cells" *(arrows)*, with inclusions resembling crumpled tissue paper.

American populations. Type 1 disease displays marked phenotypic variability in its age at onset, rate of progression, and degree of visceral organ involvement. Although survival may be reduced, individuals may live well into adulthood.[33] Indeed, patients have been diagnosed coincidentally in the sixth to eighth decades of life, and with particular genotypes the manifestations may be so minor that affected patients do not seek medical attention.[31]

Gaucher disease types 2 and 3 are primary neuronopathic variants distinguished by the age of onset and severity of CNS features. Although infrequent in European and North American populations, they are more commonly seen in Asia, Africa, and South and Central America. The demarcation between Gaucher disease types 2 and 3 is clinically useful but somewhat arbitrary insofar as these variants represent a continuum of disease phenotypes. Gaucher disease type 2 is a severe, early (prenatal to first 6 months of life) onset, rapidly progressive neurologic disease, particularly with brainstem abnormalities (stridor, dysphagia, aspiration) and visceral disease. Death occurs in the first 1 to 2 years of life. Gaucher disease type 3 has a more protracted course, with variable CNS and visceral organ (e.g., hepatosplenomegaly, poor weight gain) involvement. Indeed, horizontal supranuclear gaze palsy and minor cognitive deficits may be the only manifestations of neurologic disease for decades. Survival is shortened, with death usually occurring by the fourth decade of life.[31]

Although Gaucher disease type 2 demonstrates similar visceral findings to types 1 and 3, only the findings in Gaucher disease type 1 are presented here. The visceral findings in types 1 and 3 are very similar. It is important to note that types 1 and 3 can present in the first few years, and therefore the distinction between types 1 and 3 is not based on age at onset but rather by the presence of early primary CNS involvement in type 3.

Hematologic abnormalities are common in individuals with Gaucher disease type 1. Thrombocytopenia of mild to moderate severity is the most common finding in the peripheral blood and is seen in 50% to 70% of individuals at diagnosis.[31] Splenic sequestration and diminished platelet production caused by bone marrow infiltration are implicated as mechanisms. Splenectomy improves platelet counts; however, this is generally not advised because of the associated risks, as described later.

Anemia is present in approximately 20% to 30% of clinically involved individuals at diagnosis, although this varies with *GBA1* genotype.[31] The anemia is generally mild and is normocytic or microcytic and hypochromic. In developing countries severe anemia in individuals with Gaucher disease may be multifactorial, and additional contributing factors should be sought.[31] Low serum iron levels and iron-binding capacity resemble the anemia of chronic disease, but excessive iron is present in bone marrow Gaucher cells. Ferritin levels are generally elevated, likely owing to the inflammatory component of Gaucher disease. Iron therapy is generally not useful, but a short trial of iron may provide insight into its utility. Megaloblastic anemia occurs with vitamin B_{12} deficiency, which may be more frequent in this disease; evaluation for vitamin B_{12} deficiency should be considered, with appropriate treatment as indicated. Anemia requiring blood transfusions is unusual in developed countries.[31]

Coagulation factor abnormalities are common, including abnormalities of factor IX, vWF Ag, and factor VIII. These rarely require clinical intervention and may be incidental findings.[34-36] Deficiencies of factor XI are frequent, particularly in the Ashkenazi population.[31]

Leukopenia is atypical but may occur with severe splenomegaly or bone marrow failure caused by myelofibrosis.[31] Recently, the roles of excessive cytokine and chemokine have been recognized as important to the pathology of Gaucher disease. This is because of the recruitment and chronic stimulation of immune system cells, including B- and T-lymphocytes.[37] The long-term stimulation of B-cells and their precursors lead to monoclonal and oligoclonal gammaglobulinemias and an increased rate of multiple myeloma in adults. Autoimmune hemolytic anemia occurs infrequently[36]

Most patients (75% to 90%) have bone abnormalities on radiographic imaging.[31] At least half have an Erlenmeyer-flask deformity, in which expansion of the femoral midshaft leads to a tapered appearance and widening of the distal end. Destruction of the marrow cavity (resulting from marrow replacement by Gaucher cells), cortical lytic lesions (caused by infarctions), and osteopenia or osteoporosis are present in many patients. Painful bone crises, similar in clinical manifestations to bone infarcts in sickle cell disease, occur in approximately 10% of patients and are more frequent in the femoral head and shaft. These episodes can mimic osteomyelitis, with fever, local erythema, leukocytosis, and increased erythrocyte sedimentation rate. Growth retardation occurs in 35% to 40% of children, leading to a reduction in predicted adult height.[38-40]

Hepatomegaly is nearly universal in Gaucher disease types 1 and 3, although the degree of enlargement is variable, ranging from 1.25 to greater than eightfold of predicted normal volumes. The liver is usually homogenous, with evidence of fatty infiltration on magnetic resonance imaging (MRI) studies, but isolated areas of Gaucher cell accumulations do occur and may raise the suspicion of malignancy. Persistent mild elevations in serum transaminases and increased unconjugated bilirubin are not infrequent; however, liver failure is rare and is associated with other comorbidities, including hepatitis C.[31] Hepatocellular carcinomas and cholangiosarcomas have occurred, but these are unusual and confined to the adult population.

Asymptomatic splenomegaly is the most frequent presenting sign. Splenomegaly may be sufficiently pronounced to result in early satiety or to interfere mechanically with respiratory function.[31] As evaluated by MRI or ultrasound, the spleen is generally homogeneously enlarged early in life. With increasing size and age, the spleen can develop infarctions, multiple areas of scarring, and intrasplenic nodules. The scarred or damaged areas may lead to intrasplenic consumption of coagulation factors. In adults malignancy should be excluded.[41] Although infrequent, pain from splenic infarction may mimic an acute abdomen. Splenectomy rapidly improves the hematologic signs, but it is generally not recommended because it has been linked to worsening bone disease and increased frequency of pulmonary hypertension.

Several variants of pulmonary involvement occur in Gaucher disease type 1, but they are much more frequent in type 3. These include interstitial infiltrative disease, alveolar infiltration, hepatopulmonary syndrome, and pulmonary hypertension and are associated with significant morbidity and mortality risk.[31] The infiltrative diseases are more common in younger patients with type 3 disease and can be exacerbated by chronic aspiration. Pulmonary vascular disease is associated with adult female, non-Jewish patients who have undergone splenectomy. These complications can be challenging to treat and require medications for pulmonary hypertension as they respond poorly to enzyme therapy.[31,42]

Specific malignancies have a clearly increased frequency in adults with Gaucher disease type 1. These include multiple myeloma and lymphoid cancers (i.e., leukemia, Hodgkin and non-Hodgkin lymphoma).[43-46] The lifetime risk of multiple myeloma in untreated type 1 disease is estimated to be approximately 25 times that of the general population.[46] The overall cancer risk in patients with Gaucher disease is estimated at 1.8 times that of the general population.[46] However, the significance of this and the relationship to Gaucher disease is unclear. There are no data to support an increased risk of malignancy in children with types 1 and 3 diseases.

Gaucher cells are the hallmark histologic findings in all variants of Gaucher disease. These lipid-laden macrophages are approximately 20 to 100 μm in diameter, with tubular inclusions resembling crumpled tissue paper (see Fig. 25-3). This material stains positively with periodic acid–Schiff (PAS) stain. In comparison, storage cells in sphingomyelinase deficiency (discussed later) contain foamy-appearing inclusions. On electron microscopy Gaucher cells demonstrate membrane-bound inclusions containing twisted structures (Fig. 25-4). Histologic analysis of bone marrow demonstrates accumulation of Gaucher cells and fibrosis; the latter can be progressive.[31]

Clinical features suggest the diagnosis of Gaucher disease, as does the presence of Gaucher cells in tissue (i.e. bone marrow, liver, spleen) or bronchoalveolar lavage. Confirmatory laboratory diagnosis requires demonstration of decreased acid β-glucosidase activity in nucleated cells or tissues, most commonly peripheral blood leukocytes or cultured skin fibroblasts. Molecular diagnosis through the identification of pathogenic mutations in both copies of *GBA1* can provide useful prognostic information. Although genotype and phenotype correlations are not absolute, identification of known mutations may provide insight into the potential severity and risk of CNS or non-CNS disease. For example, the presence of a *GBA1* mutation encoding N370S in affected individuals is not associated with early onset progressive, primary neurologic disease. Homozygosity for N370S generally predicts a less severe disease course than other genotypes. About 50% of N370S homozygotes are predicted never to come to medical attention owing to their lack of overt signs and symptoms. For example, N370S homozygotes have an age of onset or recognition of about 32 years, whereas in individuals with the N370S/84GG (null), onset occurs by approximately 6 years. In addition, the latter genotype is associated with greater liver and spleen enlargement. Homozgyosity for the recurrent allele encoding L444P is highly associated with early onset primary CNS disease. An extensive review of these correlations from large patient populations is available.[31]

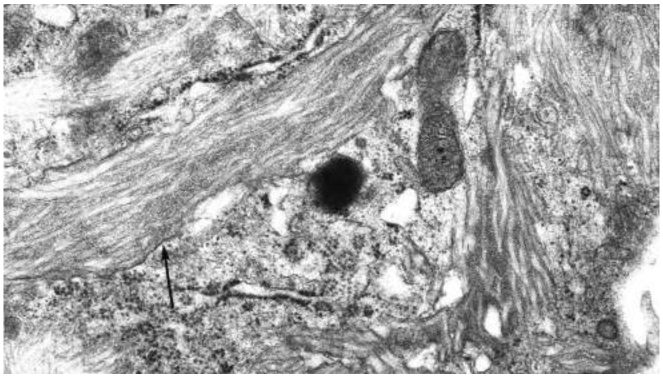

Figure 25-4 Gaucher inclusions. Electron micrograph of a Gaucher cell demonstrating characteristic membrane-bound twisted inclusions of glucosylceramide and phospholipids *(arrow)*.

Recommendations from expert panels regarding evaluation, monitoring, and treatment of patients with Gaucher disease are available and revised on a regular basis.[47-49] Gaucher disease variants are multisystem diseases that affect disease management plans. The lack of predictive biomarkers necessitates comprehensive, multidisciplinary evaluations of the major organs for associated complications. The primary focus is on the major involved organs (liver, spleen, blood, and bone) and their functions.

Although HSCT has been used to treat type 1 disease, its utility is limited by the availability of safer, specific forms of therapy. Because acid β-glucosidase is not normally secreted from cells, HSCT has not shown significant or consistent effects on the CNS manifestations in type 3 disease. Similarly, HSCT in type 2 disease has not been successful for the CNS disease.

Two treatment approaches are currently available for the treatment of Gaucher disease type 1: enzyme replacement therapy (ERT) and substrate reduction therapy (SRT). With ERT recombinant human acid β-glucosidase, a glycoprotein, is administered intravenously. For Gaucher disease the available ERT products have been modified to expose terminal α-mannosyl residues for preferential targeting to the macrophage mannose receptor. After intravenous administration such modified enzymes preferentially localize to the macrophage compartment, are internalized by receptor-mediated endocytosis, and delivered to the lysosomes where they reconstitute the enzyme activity. This leads to degradation of the stored glucocerebroside and other glucolipids. SRT is different and depends on the presence of some residual mutant enzyme activity (1% to 15%) that can degrade a lesser amount of substrate and establish a healthier steady state. The driving concept is to slow the synthesis of the offending substrates by inhibition of their synthesis. The target is the Golgi localized enzyme, glucosylceramide synthase. For either ERT or SRT, the efficacy will be limited by tissue delivery and penetration. For example, the ERT recombinant enzymes are macromolecules that do not penetrate the blood-brain barrier, or potentially other tissue barriers, in sufficient quantities to be therapeutic. The SRT small molecules may or may not be distributed to all tissue and can have off-target effects.

ERT is currently the standard of care for the treatment of Gaucher disease. Three ERT products are currently approved: Imiglucerase (Cerezyme, Genzyme, a Sanofi company, Cambridge, Mass., approved by the Food and Drug Administration [FDA] in 1991), velaglucerase alfa (VPRIV, Shire Human Genetic Therapies, Inc., Cambridge, Mass., approved by the FDA in 2010), and taliglucerase alfa (Elelyso, Pfizer, Inc., New York, N.Y., approved by the FDA in 2012). The FDA currently restricts the use of taliglucerase alfa to adults (older than 18 years). These products differ in their manufacturing processes, glycosylation patterns, and amino acid sequence. Briefly, they are all human acid β-glucosidases that are produced in large cultures of Chinese hamster ovary cells (imiglucerase), human fibrosarcoma cells (velaglucerase alfa), or carrot root cells (taliglucerase alfa). All have terminal α-mannosyl residues and target the macrophage mannose receptor; have highly similar crystal structures; and have similar, if not identical, enzyme functions. On the basis of current data, all three ERT products have similar clinical effects and safety. Direct head-to-head studies of imiglucerase and velaglucerase alfa were conducted in mouse analogs of Gaucher disease and shown to have similar biochemical, histopathologic, and antibody formation effects.[50]

The long-term (approximately 20 years) safety and efficacy of imiglucerase has been shown in Gaucher disease type 1.[51,52] In 1028 such patients, hemoglobin concentrations increased to normal or near normal within 6 to 12 months, with a sustained response through 5 years. In thrombocytopenic patients with intact spleens, improvements in platelet counts were particularly noted during the first 2 years of therapy. Further increases in platelet counts were observed during years 2 through 5; The likelihood of achieving a normal platelet count decreased with increasing severity of baseline thrombocytopenia. Similarly, significant decreases in liver (20% to 30%) and spleen (30% to 50%) volumes were noted after 2 years, with additional reductions in liver volume to near normal levels by 5 years. Further decreases in spleen volume after two years were minimal.[51] Improvement or stabilization of bone pain occurred in many patients after 2 years of therapy, with approximately a third of patients having residual bone pain reports, probably the result of chronic joint abnormalities that are not directly related to Gaucher disease. A 10-year follow-up of patients treated with imiglucerase showed sustained stability of disease.[52] The safety profile of imiglucerase has been extensively reviewed and shows that the drug is generally safe and well tolerated.[51,52] A detailed statistical study of various doses of imiglucerase shows a clear dose response of the major monitoring parameters and provides guidance for expected responses in patients initiated on any dose between 15 to 60 U/kg every two weeks.[53] Bone mineral density was also dose dependent over the long term.[54] About 13% of patients receiving ERT with imiglucerase develop immunoglobulin G (IgG) antibodies, and about half of these patients have minor adverse events or infusion-related events. These are generally easily controlled. Inhibitor antibodies have been reported in a few patients,[55,56] and immunoglobulin E (IgE) antibodies have been anecdotally reported in fewer than 10 patients. Similar long-term data are not available for velaglucerase alfa and taliglucerase alfa, but phase II and phase III studies show comparable safety and efficacy profiles to imiglucerase.[57-61]

SRT with miglustat (Zavesca, Actelion Pharmaceuticals, South San Francisco, Calif.) is licensed in several countries for use in adults with mild to moderate Gaucher disease type 1 for whom ERT is unavailable or contraindicated. Miglustat is an oral medication that produces statistically significant effects on liver and spleen volumes but only slight improvements in hematologic variables.[62-64] Miglustat is reported to positively affect bone mineral density.[65] The drug has several side effects, including diarrhea (approximately 80%) and peripheral neuropathy, which may be significant in some patients.[66]

Phase I and phase II clinical studies on a second SRT, eliglustat tartrate (Genzyme, a Sanofi company; Cambridge, Mass.), have been completed, and initial phase III results are available.[67-69] In the phase II study, 20 patients completed a total of 2 years of therapy. In these patients statistically significant improvements from baseline were observed for platelet count, hemoglobin level, spleen volume, liver volume, and bone mineral density of the lumbar spine. These findings were essentially duplicated in the initial phase III data in patients who were naïve to therapy. Also, the drug was well tolerated, without many of the side effects observed in miglustat.[68,69]

Acid Sphingomyelinase Deficiency (Niemann-Pick Disease Types A and B)

The acid sphingomyelinase (ASM) deficiencies are a group of clinically heterogeneous, autosomal recessive conditions, characterized by deficient activity of ASM resulting from mutations in *SMPD1*. Sphingomyelin, a phosphosphingolipid, accumulates in lysosomes of multiple cell types, particularly those of the macrophage or monocyte lineage, leading to characteristic lipid-laden Niemann-Pick foam cells (Fig. 25-5).[70]

Two specific variants of ASM deficiency are classically recognized. Niemann-Pick A (NPA) is an early onset neurologic disorder characterized by progressive psychomotor retardation, ocular findings (cherry-red spots [approximately 50%]), massive hepatosplenomegaly, and cachexia, leading to death in the first few years. A nonneurologic form (NPB) involves visceral disease and is compatible with survival into adulthood.[71] The NPB phenotype includes growth retardation, hepatosplenomegaly, infiltrative pulmonary disease, pancytopenia, skeletal disease, hypercholesterolemia, and lymphadenopathy. Intermediate phenotypes between NPA and NPB are

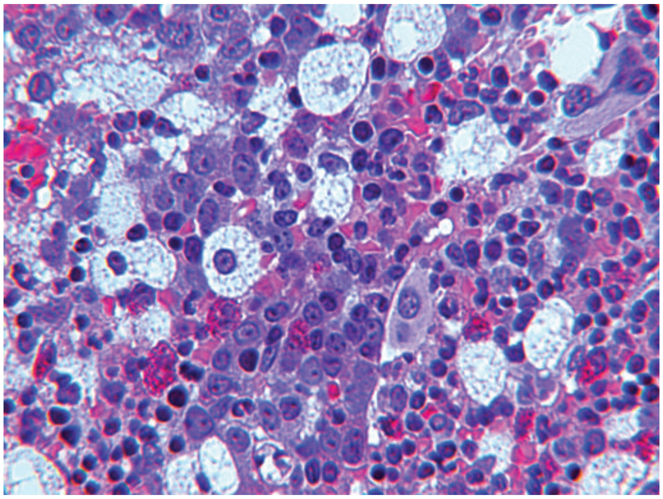

Figure 25-5 Niemann-Pick B bone marrow cells. Light micrograph of Niemann-Pick B bone marrow with characteristic lipid-laden vacuoles, which impart a foamy appearance to cells of macrophage/monocyte origin, "Niemann-Pick cells." These cells may stain a bluish color with Giemsa and are occasionally referred to as *sea-blue histiocytes*. *(Courtesy Dr. Kevin Bove.)*

frequently described. As with many LSDs, ASM deficiencies represent a disease continuum.

The incidence of the various forms of the disease varies among different populations. Based on long-term experience in Australia, the estimated combined frequencies of NPA and NPB are approximately 1 in 248,000.[32] NPA is more prevalent in the Ashkenazi Jewish population, in which approximately 1 in 80 persons are heterozygotes.[70] NPB is panethnic, with the highest incidence in individuals of Middle Eastern and North African descent. Emerging data suggest greater frequencies in Brazil, but better ascertainment is needed.

NPA presents somewhat uniformly and includes severe progressive neurovisceral disease within the first few months of life. Neonatal jaundice, hepatomegaly (usually in the absence of liver dysfunction), splenomegaly, and failure to thrive are present early. Moderate lymphadenopathy and infiltrative pulmonary disease are frequently seen. Moderate microcytic anemia, which may respond to iron supplementation, and thrombocytopenia develop progressively. During the subsequent months neurodevelopmental arrest is followed by regression, hypotonia, muscle weakness, and ultimately spasticity and rigidity as terminal stages. Ophthalmologic examination may reveal cherry-red maculae in approximately 50% of subjects. Death usually occurs by 2 to 3 years of age.[71]

NPB is a heterogeneous disease with manifestations generally restricted to the visceral organs. Most patients are diagnosed in childhood, often after hepatosplenomegaly is found on routine examination.[70] Hepatosplenomegaly is most prevalent during childhood and less so in adults. The mean liver and spleen volumes are 1.9±0.7 MN [range: 0.7-3.9 MN (MN=calculated multiples of normal)] and 11.1±5.7 MN (range 3.1-27.3 MN), respectively. About 71% of individuals had liver volumes greater than 1.5 MN, whereas 84% of individuals had spleen volumes greater than 5 MN.[72] Splenectomy has been performed in the past, particularly in those with a history of bleeding and thrombocytopenia. The removed spleens are bright orange as a result of the sphingomyelin accumulation. Splenectomy is generally discouraged because of concerns that disease severity may worsen in other organs, such as the lung, and the risk of infection related to splenectomy.

Atherogenic serum cholesterol and lipoprotein profiles include low high-density lipoprotein (HDL), and elevated total cholesterol, triglycerides, low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) levels. These are present from early childhood. Additionally, easy bruising and bleeding, infiltrative pulmonary disease, and joint or limb pain (or both) are common. Some individuals have significant bleeding (i.e., epistaxis, postsurgical bleeding) and may require medical intervention, including surgical procedures and blood transfusions. Thrombocytopenia is the most common hematologic finding, followed by anemia and leukopenia. These hematologic abnormalities are generally mild to moderate. In a cross-sectional study of patients with NPB, mean hemoglobin and hematocrit concentrations were 13.3 g/L (SD 1.5; range 9.3-16.5) and 39.1% (SD 4.5; range 27.8-48.3), respectively, whereas mean white blood cell (WBC) and platelet counts were 6.4 × 109/L (SD 2.7; range 2.1-16.2) and 158 × 109/L (SD 82; range 59-459).[72] Osteoporosis, expansion and widening of the medullary cavities, and remodeling defects can be demonstrated radiologically. Survival into adulthood is common, as is development of liver cirrhosis and fibrosis and pulmonary dysfunction.

Although NPB is not generally associated with primary neurologic involvement, a subset of such patients may have exhibit retinal abnormalities, including cherry-red maculae or a gray, granular pigmentation around the fovea. Cognitive impairment has been found with or without other neurologic findings.[72] These findings highlight the continuum of Niemann-Pick disease variants, rather than discrete subtypes.

Niemann-Pick cells, a primary histologic finding in ASM deficiencies, are approximately 25 to 75 μm in diameter. The cytoplasm is filled with lipid vacuoles, imparting a foamy appearance to the cells (Fig. 25-5).[69] The vacuoles stain positive with Sudan black B and oil red O but poorly with PAS. Within the bone marrow the intracellular material in Niemann-Pick cells may have a bluish color on Giemsa staining and are occasionally referred to as *sea-blue histiocytes*. Sphingomyelin also accumulates in hepatocytes, with inflammation and fibrosis that can lead to cirrhosis (Fig. 25-6). Alveolar histocyte-like cells filled with sphingomyelin accumulate in the lung.

ASM deficiency is suspected on the basis of the clinical features and identification of Niemann-Pick cells on histologic examination of tissues. The diagnosis is confirmed by deficient ASM activity in any nucleated cell sample or identification of pathogenic mutations in both copies of *SMPD1*. Of note, the type and severity of disease correlate poorly with the amount of in vitro residual enzyme activity.

No specific treatments for NPA or NPB are currently approved. Treatment is supportive. HSCT has been performed in patients with NPA and NPB. Despite engraftment, continued neurologic deterioration occurs in NPA. HSCT has been disappointing in NPB. Variable effects have been seen on the liver and lung manifestations. Two well-documented cases are instructive. Both showed improvement or resolution of pulmonary disease but no correction of hepatocellular disease despite resolution of Kupffer cell involvement. Indeed, both patients progressed to cirrhosis.[70,73-76] A phase I clinical trial evaluating the safety of ERT in NPB adults has been completed, and a phase II trial is currently being conducted.

Niemann-Pick Disease Type C

Niemann-Pick disease type C (NPC) is a clinically heterogeneous progressive neurovisceral disease resulting from mutations of *NPC1* (~95% of cases) or *NPC2* (~5% of cases) and is inherited in an autosomal recessive manner.[77] Although the major phenotypic manifestations are common to both NPC1 and NPC2, severe pulmonary disease is a unique complication and a significant source of morbidity in patients with *NPC2* mutations. NPC was originally thought to be part of the NPA and NPB family, but the identification of the molecular lesions and the role of NPC proteins in cholesterol metabolism revealed a different underlying biology. However, the nosology is prevalent in the literature and has been retained.

NPC, which is panethnic with a frequency of approximately 1 in 120,000 to 1 in 150,000,[77,78] is characterized by defective lipid transport and lysosomal accumulation of lipids (unesterified cholesterol, phospholipids, sphingomyelin, and glycolipids) in affected cells. The gene products of *NPC1* and *NPC2* are lysosomal proteins that are critical to the egress of cholesterol from lysosomes for the modulation of cellular lipid metabolism by way of the SREBP system.[79] Although partial deficiencies of ASM activity have been found in NPC patient cells, this is not the primary defect.

NPC has three variants, based on the age of onset, severity of CNS disease, and survival: neonatal/infantile, childhood, and adolescent/adult.[80] As with many LSDs, overlap exists among the various clinical forms, thereby forming a continuum of overlapping disease phenotypes.

Progressive neurologic or psychiatric manifestations and visceral (liver, spleen, and potentially lung) involvement occur in any of the variants. It is important to note that visceral findings may occur before or after the development of neurologic symptoms, and in adults visceral findings may be minimal at diagnosis. The age of onset of systemic involvement does not correlate with neurologic involvement. The age of onset of neurologic disease correlates with disease severity and survival.[81]

The neonatal and infantile variant is a rapidly progressive neurovisceral disease with onset in the first few months of life and accounts for approximately 20% to 30% of cases.[82,83] The most severe cases may present perinatally with ascites or hydrops fetalis (Table 25-1).[78] Infantile cholestatic disease or idiopathic neonatal hepatitis often develops in early infancy and is a common cause of neonatal liver disease. In approximately 10% of cases, fulminant liver disease develops and can lead to death.[84] Survivors usually experience resolution of severe liver disease by 2 to 4 months of life; however, hepatosplenomegaly often remains and becomes less conspicuous with age.[80] Failure to thrive and growth retardation are prominent. A subset of NPC2 individuals develops significant pulmonary disease, characterized by tachypnea, infiltrates on chest x-ray, and a presentation resembling alveolar proteinosis.

Those recovering from early liver disease experience progressive neurodegenerative and exhibit hypotonia, developmental delay, regression, spasticity, dystonia, dysphagia, seizures, and pyramidal signs.[77,80,82,85] Vertical supranuclear gaze palsy is a classic finding for NPC variants. Death usually occurs by 5 years.[81]

Childhood-onset NPC is the most common variant, accounting for approximately 50% to 70% of cases. These children initially appear healthy, with normal development. By early to late childhood, they exhibit neurologic deterioration manifested initially as clumsiness and gait abnormalities, behavioral problems, poor academic performance, and supranuclear gaze palsy. Gradual progression of neurodegenerative signs occurs, including psychiatric disturbances, ataxia, dystonia, seizures, cataplexy, dysarthria, and dysphagia. Individuals eventually become incapacitated. Death usually occurs in the second or third decade of life, usually from pneumonia.[80] Significant liver dysfunction is unusual in this variant.

The adolescent- or adult-onset variant accounts for approximately 5% to 10% of cases.[82,83] This variant manifests primarily as a psychiatric or neurocognitive degenerative disease in which significant visceral involvement is unusual, although hepatosplenomegaly may occur.[77] Hematologic abnormalities are not commonly present. Vertical supranuclear gaze palsy may be subtle and difficult to recognize.

TABLE 25-1 Fetal Hydrops Associated with Lysosomal Storage Diseases

Diagnosis	Fetal Features	Neonatal Findings	Pathology	Diagnostic Confirmation
Morquio IV A	Ascites, pleural effusion	May resolve by term		Reduced *N*-acetylgalactosamine-6-sulfatase activity
Mucopolysaccharidosis VII	Nuchal thickening, ascites	Coarse features	Vacuoles in lymphocytes and placenta	Reduced β-glucuronidase activity
Gaucher	Hydrops, hepatomegaly, fetal hypokinesia	Collodion-like skin, contractures, hepatosplenomegaly	Gaucher cells	Reduced acid β-glucosidase activity
Niemann-Pick A	Nuchal thickening, hydrops	Hepatomegaly, prolonged jaundice, poor feeding	Foam cells	Reduced sphingomyelinase activity
Niemann-Pick C	ascites	Prolonged jaundice, pulmonary infiltrates	Foam cells	Abnormal filipin staining, molecular testing for *NPC1* and *NPC2*
GM_1 gangliosidosis	Intrauterine growth retardation, oligohydramnios	Hypertonia, periorbital edema, cherry red spots	Placental vacuolization	Decreased β-galactosidase, normal neuraminidase activities
Galactosialidosis	Hydrops	Edema, coarse facies, hepatosplenomegaly, telangiectasias	Vacuoles in circulating cells, Kupffer cells, other organs	Decrease in *both* β-galactosidase and neuraminidase activities
Infantile sialic acid storage disease	Ascites, IUGR, nuchal thickening	Hepatomegaly, coarse facies, hypotonia, stippled epiphyses	Placental vacuolization	Increased free sialic acid in urine, amniocytes, fibroblasts
Mucolipidosis II	Short femurs	Gingival hyperplasia, coarse facies, periorbital puffiness, hepatosplenomegaly	Vacuoles in lymphocytes, not present in bone marrow	Increase in various lysosomal enzymes in plasma

Histologic analysis of bone marrow reveals characteristic foam cells containing accumulated free cholesterol, as evidenced by filipin positivity, and sphingolipids (Fig. 25-7).[77,81] Sea-blue histiocytes may be present.[81] These cells are also present in other visceral organs (hepatocytes in the liver) and CNS (neurons and glial cells). Ultrastructurally, the storage material consists of pleomorphic membrane-bound lipid inclusions with structures varying from crystalline to electron-dense laminated inclusions.[84,86,87]

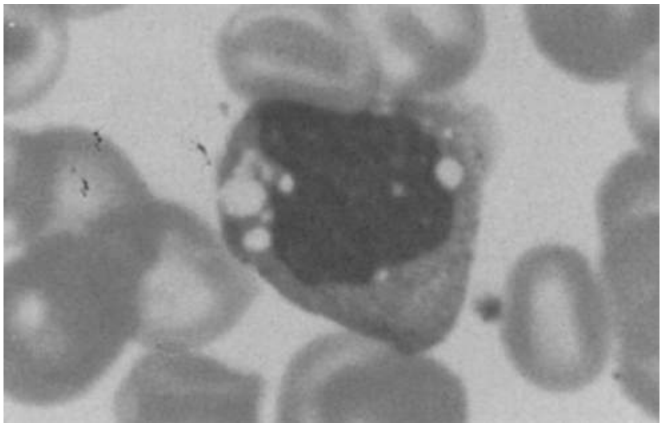

Figure 25-7 Niemann-Pick C peripheral blood leukocyte. Characteristic lipid laden "foam cell" in peripheral blood of a patient with Niemann-Pick disease type C. *(Courtesy J. Alroy, Department of Pathology, Tufts New England Medical Center.)*

Because of the significant variability of phenotypes, NPC is not always initially considered in the differential diagnosis. Indeed, the diagnosis may be delayed as a result of the absence of hepatosplenomegaly or storage cells in the bone marrow. A biochemical diagnosis is established by demonstration of impaired cholesterol esterification and positive filipin staining in cultured fibroblasts. ASM activity is normal to low. Molecular studies can provide a definitive diagnosis; Many *NPC1* or *NPC2* mutations are confined to single families.

Treatment of NPC is supportive. Bone marrow transplantation may improve visceral disease but is ineffective for CNS disease.[88] As the NPC1 protein is an integral lysosomal membrane protein with multiple transmembrane domains, it is not secreted and therefore cannot cross-correct neighboring cells. For similar reasons, liver transplantation does not benefit patients with CNS disease.

A number of pharmacologic agents have been evaluated as potential therapies for NPC, including cholesterol-lowering medications (statins), sterol-binding agents, and glucocorticoids, all without success. The safety and efficacy of miglustat (Zavesca®, Actelion Pharmaceuticals) has been evaluated in NPC1 and may stabilize oculomotor manifestations, dysphagia, and ambulation deficits. However, the effects on visceral disease manifestations in NPC were not significant.[89-92] Side effects were similar to those discussed previously and included diarrhea, flatulence, and abdominal pain. The European Medicines Agency (EMA) approved Miglustat in 2009 for the treatment of CNS manifestations in NPC. It is not approved by the FDA.

Cyclodextrin, a cholesterol-binding excipient, is being explored as a therapy for NPC. This agent is theorized to reverse the transport defect in the late endosomal or lysosomal complex, allowing sequestered free cholesterol to be transported out of the lysosome and metabolized by other cellular mechanisms.[93] Based on encouraging preclinical studies in the *Npc1-/-* mouse model, clinical trials in humans have begun.[94]

Farber Disease (Lipogranulomatosis)

Farber disease is a very rare progressive autosomal recessive disease resulting from deficient activity of acid ceramidase, which is encoded by *ASAH1*. The frequency is estimated to be less than 1 in 1,000,000.[94] Seven subtypes of Farber disease are recognized; these vary in severity and survival. Types 6 and 7 are not caused by mutations in *ASAH1* and will not be discussed here.

Classic Farber disease, the most common variant, is characterized by a triad of progressive clinical manifestations: painful and progressive deformation of joints; subcutaneous nodules, particularly near the joints and over pressure points; and progressive hoarseness resulting from laryngeal nodules. Often these findings are present within the first few weeks to months. Progressive respiratory and swallowing difficulties result in poor weight gain and impaired acquisition of development milestones; this can necessitate palliative management (i.e., tracheostomy and gastrostomy tube placement). Granulomatous lesions may also occur in the liver, spleen, lung, heart, reticuloendothelial system, bone, and CNS and contribute to the morbid manifestations. Hepatomegaly may be identified in patients. Death usually occurs within the first years of life.[94]

Intermediate and attenuated variants demonstrate similar, albeit less severe, phenotypes. Clinical manifestations begin within the first 1 to 2 years; some individuals have survived into adulthood.[94]

The neonatal-visceral variant is characterized by hepatosplenomegaly first noted in the neonatal period. In the most severe cases, patients may present with nonimmune hydrops fetalis. Infants with this severe phenotype die in early infancy, often before the onset of the more characteristic clinical features of classic Farber disease.[94]

The neurologic form is defined by progressive neurodegeneration noted within the first two years, followed by death shortly thereafter. Visceral organ involvement, including subcutaneous nodules and joint involvement, may be present but does not predominate.[94]

The principal pathologic findings are granulomatous infiltrates composed of foam cells containing a PAS-positive material that is extractable with lipid solvents. Comma-shaped curvilinear tubular, membrane-bound structures (Farber bodies) (Fig. 25-8) within vacuoles are characteristic findings on electron microscopy.

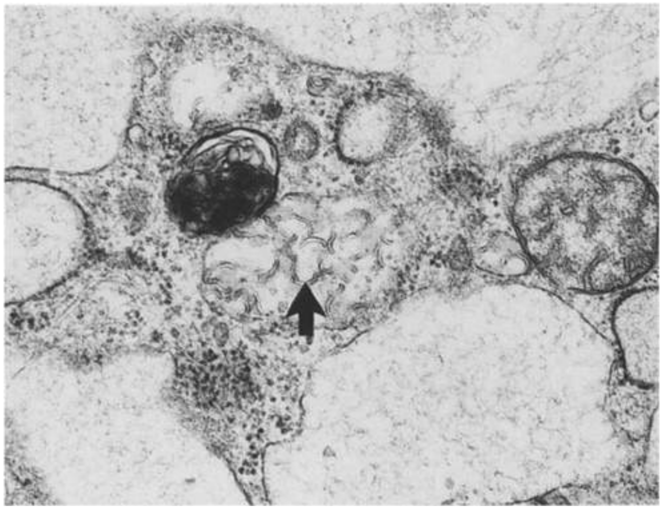

Figure 25-8 Farber cell body. Conjunctival biopsy showing a vacuole filled with tubulelike profiles of "curvilinear" bodies (Farber body). Uranyl acetate and lead citrate × 42,000. *(From Nowaczyk et al:* J Inherit Metab Dis *19:655–660, 1996.)*

The clinical features and presence of characteristic Farber bodies on histology suggest the diagnosis of Farber disease. Definitive diagnosis relies on identification of deficient acid ceramidase activity in leukocytes or cultured skin fibroblasts or by molecular analysis.

Treatment of Farber disease is supportive (i.e., tracheostomy or resection of oral granulomas for management of upper airway obstruction). HSCT in several individuals who had classic Farber disease with neurologic involvement resulted in improved visceral features, but neurologic deterioration continued, leading to death.[95,96] Several Farber disease patients without neurologic involvement have received HSCT and displayed improvement in visceral disease. These children were reported as alive and well without any evidence of neurologic deterioration.[97] Thus individuals without neurologic involvement may benefit from HSCT.

GM_1 Gangliosidosis

GM_1 gangliosidoses are heterogeneous, progressive neurovisceral disorders resulting from a deficiency of the enzyme acid β-galactosidase because of mutations in *GLB1*. There are several lysosomal β -galactosidases with different substrate specificities. In the GM_1 gangliosidoses, acid β-galatosidase deficiency leads to specific accumulation of GM_1ganglioside, asialo-GM1 ganglioside, oligosaccharides, and keratin sulfate in neurologic and visceral tissues.[98]

The GM_1 gangliosidoses are allelic to Morquio type B disease, a nonneurologic mucopolysaccharidosis primarily expressed as a skeletal dysplasia with a paucity of other visceral organ involvement. GM1 gangliosidosis has a phenotype similar to that of galactosialidosis, because acid β-galactosidase exists in multienzyme complex with N-acetylgalactosamine-6-sulfatase, neuraminidase, and protective protein cathepsin A (PPCA), and the defects in PPCA lead to deficiencies of all three enzymes.[98]

GM_1 gangiosidosis presents in three forms depending on the age of onset, severity of neurologic disease, presence or absence of visceral disease, and survival: early infantile onset (type 1), late infantile onset (type 2), and adult onset (type 3).[98] The conditions are panethnic but appear to be more common in certain populations, including those in Brazil and the Maltese Islands, and among Romani and Cypriot people.[77] The prevalence was estimated at approximately 1 in 384,000.[32]

Early infantile onset (type 1) GM_1 gangiosidosis, the most severe variant, usually manifests in the first 6 months after birth. In rare cases intrauterine growth retardation and oligohydramnios have been present. The most severe variant presents as fetal hydrops. More frequently, children exhibit feeding problems, failure to thrive, splenomegaly, hepatomegaly (with or without evidence of hepatic dysfunction), and coarsening of facial features. Generalized skeletal dysplasia may be present as joint stiffness. Developmental arrest occurs during the first few months, followed by progressive neurodegeneration. Cherry-red maculae are commonly observed and are an important clue to this diagnosis. Death usually occurs by 3 years of age, frequently as a result of pulmonary infections.[98]

Late infantile or juvenile onset (type 2) GM_1 gangliosidosis manifests from approximately 6 months to 3 years of age with developmental arrest, followed by progressive neurodegeneration. The patients may exhibit other visceral organ manifestations, including hepatosplenomegaly and skeletal involvement. Cherry-red maculae are variably present. Survival may extend into the second decade.[98]

Adult onset (type 3), or chronic, GM_1 gangliosidosis is a slowly progressive, heterogeneous CNS disease, with a variable age of onset from 3 to 30 years. Neurologic features frequently include gait disturbances, speech disturbances, dystonia, and Parkinsonism. Skeletal changes are less significant than in the more severe variants, and hepatosplenomegaly and cherry-red maculae may not be present.[98]

Blood cell counts are generally normal. The reticuloendothelial system contains foamy histiocytes filled with strongly PAS-positive granular material. Vacuolated lymphocytes can readily be recognized in peripheral blood and bone marrow, which may contain sea-blue histiocytes.[99] Additionally, lymphocytes and neutrophils may exhibit basophilic granules that stain mildly with toluidine blue.[98] Tissue macrophages with grossly distended cytoplasm filled with storage lysosomes can be identified in most organs, including the liver, kidney, spleen, lymph nodes, thymus, lung, intestine, pancreas, and skeletal muscle.[100]

GM_1 gangliosidosis is often first suspected clinically and by the detection of complex urinary oligosaccharides and glycosaminoglycans (i.e., keratin sulfate), but this is not diagnostic. Confirmation requires detection of deficient acid β-galactosidase activity in lymphocytes, fibroblasts, or plasma; however, in those with deficient acid β-galactosidase activity, subsequent neuraminidase assays are necessary to rule out galactosialidosis. Confirmation of the diagnosis may also be made by identification of a pathogenic mutation in each copy of *GLB1*.

Treatment of GM_1 gangliosidosis involves management of symptoms. HSCT was unsuccessful in stabilizing or preventing neurologic deterioration in a presymptomatic child with juvenile-onset disease, despite normalization of enzyme activity in WBCs.[101]

GM_2 Gangliosidosis, β-Hexosaminidase Deficiency Variants

The GM_2 gangliosidoses are heterogeneous neurodegenerative diseases, inherited in an autosomal recessive manner and characterized by impaired degradation of GM_2 ganglioside. This may result from deficient β-hexosaminidase activity or, more rarely, defects in the GM_2 activator protein, which is responsible for presenting the substrate to the enzyme. GM_2 ganglioside is synthesized mostly within the CNS, and consequently storage material accumulates in neuronal cells. Depending on the nature of the mutation and the biochemistry of the β-hexosaminidase enzymes, substrates can also accumulate in the visceral organs. The two isoforms of β-hexosaminidase include β-hexosaminidase A (Hex A), a heteromer consisting of α and β subunits, and β-hexosaminidase B (Hex B), a homomer of β subunits. Therefore defects in three genes, *HEXA* (encodes the α subunit), *HEXB* (encodes the β subunit), and *GM2A* (encodes the GM_2 activator) may result in impaired β-hexosaminidase activity.[102] The α-chain defects lead to isolated deficiency of Hex A and the CNS disease Tay-Sachs disease. The β-chain defects lead to deficiencies of Hex A and B, because they share the common β subunit, and the CNS and visceral disease Sandhoff disease. Hex B has non-GM_2 ganglioside substrates, oligosaccharides, and glycoproteins, which occur in the viscera, and their accumulation results in hepatomegaly and skeletal defects.

The resultant phenotypes vary in age of onset, severity of neurologic disease, presence or absence of visceral disease, and age of death.[102] Of the variants, only *Hex B* mutations are associated with visceral involvement. The reader is referred to other sources for further information regarding *Hex A* and *GM2A* deficiency disorders.[102]

Sandhoff disease is panethnic with a frequency of approximately 1 in 384,000.[32] Three variants are frequently identified, based on the age of onset, severity of disease, and survival: infantile (classic), juvenile, and adult/late onset.

Infantile onset (classic) Sandhoff disease is virtually identical to classic Tay-Sachs disease with regard to neurologic disease. Although individuals often appear normal at birth, by approximately 3 to 5 months hypotonia and exaggerated startle responses are noted. Soon afterward, a plateau in acquisition of milestones, followed by regression of development, is noted. Decreased visual attentiveness and unusual eye movements occur, and cherry-red maculae are noted on ophthalmoscopy in almost all affected individuals. After the age of 8 to 10 months, progression of the disease is rapid. Spontaneous or purposeful voluntary movements diminish, and infants becomes less responsive to their environment. Vision deteriorates rapidly, although light and dark discrimination may remain. Although not typically present at disease onset, seizures commonly develop by the age of 1 year. Progressive enlargement of the head typically begins by 18 months of age as a result of reactive cerebral gliosis and substrate deposition. In the second year decerebrate posturing, difficulties in swallowing, and increased seizures ultimately cause the affected individual to enter an unresponsive vegetative state. Death usually occurs by the age of 2 to 4 years, typically subsequent to pneumonia.[102] Storage materials (e.g., oligosaccharides and glycosaminoglycans) accumulate in the visceral organs (i.e., spleen, liver, kidneys, bone marrow, lymph nodes) and occasionally result in organomegaly; however, evidence of visceral organ dysfunction, including hematologic abnormalities, is unusual.[102]

Later onset disease variants (late infantile or juvenile onset and chronic or adult onset variants) present from early childhood to adulthood. The features are exceptionally variable among affected individuals but are typically milder and demonstrate slower rates of progression than those seen with the classic (early infantile onset) variant. These features may include muscle weakness, speech and swallowing problems, abnormal movements, gait disturbances, and seizures. Cherry-red maculae may be observed but are less common than in the classic (early infantile onset) variant.

On histologic examination, strongly PAS-positive storage material is observed in Kupffer cells in the liver, macrophages in the spleen, lymph nodes and lung, and renal tubular epithelium. These storage cells appear vacuolated in routine hematoxylin and eosin-stained paraffin sections. The storage material in these visceral organs is composed of heterogeneous lamellar structures, some of which resemble membranous cytoplasmic bodies.[102]

Sandhoff disease variants are often first suspected on the basis of the clinical features and can be distinguished from other forms of GM_2 gangliosidosis by the presence of visceral involvement, including foam cells in bone marrow. Identification of deficient total (A and B) β-hexosaminidase activity and presence of a higher than normal percentage (>70%) of the Hex-S (α-chain trimers) are strongly suggestive of the diagnosis. Confirmation is made by identification of pathogenic mutations in both copies of *HEXB*.

Currently, the treatment for hexosaminidase B deficiency is palliative. HSCT has not reversed or stabilized neurologic involvement. Miglustat treatment of affected individuals has not forestalled neurologic deterioration.[103,104]

The Mucopolysaccharidoses

The mucopolysaccharidoses are a group of inherited disorders that result from deficiency of one or more of the lysosomal enzymes required for glycosaminoglycan (GAG) or mucopolysaccharide catabolism. GAGs are long-chain complex carbohydrates that are usually linked to protein and are major constituents of connective tissue, such as cartilage and bone. Deficiencies in the specific lysosomal hydrolases needed for breakdown of chondroitin 4-sulfate, chondroitin 6-sulfate, heparan sulfate, dermatan sulfate, keratan sulfate, and hyaluronic acid result in the accumulation of incompletely degraded GAGs within the lysosome of specific cells, resulting in alterations in cell morphology and function.

Mucopolysaccharidosis Type I (Hurler Syndrome and Attenuated Mucopolysaccharidosis I)

Mucopolysaccharidosis type I (MPS I) has been divided classically into three phenotypic categories, all of which are due to deficiency in α-L-iduronidase, a soluble M6P containing enzyme. The most severe type, MPS I H, or Hurler syndrome, manifests with clinical findings during the first year but may not be recognized until the second year. Infants with MPS I H are often large for their age and may not have obvious developmental deficits until it becomes evident that language acquisition is delayed. The coarse facial features evolve over time, and review of serial photographs can be helpful in recognizing the changing phenotype. One of the earliest symptoms may be constant noisy breathing, and it is not unusual for families to complain that their child always has a cold. Lumbar prominence, termed *gibbus,* may be one of the earliest specific features. Hernias are common, and some children are recognized because of the failure of the initial surgical repair.[105,106] Increasing head circumference, sometimes the result of a communicating hydrocephalus, develops. Corneal opacities may be present during the first year but may be difficult to see with a handheld ophthalmoscope. The skeletal abnormalities that are collectively referred to as *dysostosis multiplex* include oar-shaped ribs, anterior beaking of the vertebral bodies, lumbar kyphosis, and shortening of the metacarpals and phalanges. Contractures at the hips, knees, and ankles may not be recognized until the child is standing, and it is not unusual to note limitation in shoulder movement. Evolution of symptoms during the first year is usually associated with the severe form of MPS I, which includes progressive cognitive decline.[107] The differentiation from milder forms of MPS I is crucial because of the distinct treatment options (discussed later).

The attenuated forms of MPS I, in which cognitive development is intact, have been divided historically between Scheie syndrome (onset in late childhood or adolescence) and Hurler-Scheie syndrome (onset between ages 3 and 8 years). These attenuated forms represent a continuum of severities, and referring to both as "attenuated" MPS I has become standard. It is important to remember that from the patient's point of view none of the MPS I forms are "mild." Individuals with later onset of clinical manifestations may present (1) to the orthopedist with joint stiffness, contracture, clawhand deformity, or carpal tunnel syndrome; (2) to the ophthalmologist with corneal clouding and glaucoma; (3) to the cardiologist with valve dysplasia; or (4) to the otolaryngologist with hearing loss or obstructed breathing.

Initial biochemical assessment usually involves quantitation and characterization of urine GAGs, which should reveal significant elevation (often 10- to 20-fold) of total GAG, predominantly heparan and dermatan sulfates. Iduronidase can be measured in both circulating WBCs and cultured skin fibroblasts. A pseudodeficiency state has been described,[108] which can confuse the assessment of phenotypically normal family members and interfere with prenatal diagnosis using enzyme assay. Sequencing of *IDUA* is available and provides important information for counseling of family members as well as supporting information for the prediction of severity.[109] Prenatal diagnosis is possible and should involve molecular as well as enzyme analysis. Since early diagnosis and treatment have improved the prognosis, there is interest in population based newborn screening. Pilot programs for the detection of MPS I and other treatable LSDs are beginning in several locations.

Treatment. Cross-correction of lysosomal storage by application of the appropriate enzyme was demonstrated in vitro by Neufeld and coworkers.[110] This property has been translated into treatment for MPS I using either cell-based (HSCT) or ERT therapies. HSCT from an unaffected donor has been possible for more than 20 years. Modern marrow-donor programs and transplant techniques are improving access to transplant and are fostering durable engraftment for a much larger fraction of the eligible patients.[111,112] A combined approach, using ERT during the early phase of diagnosis and preparation for HSCT, is practical, safe, and without adverse effects on graft survival.[113,114] Neurocognitive status is expected to decline for a few months after HSCT and then stabilize. For this reason earlier diagnosis and expedited referral for HSCT are important in maximizing eventual neurocognitive outcome.[115,116] The long-term benefits for children transplanted before 2 years of age include softening of coarse features, improvement in airway manifestations, and resolution of hepatosplenomegaly. However, skeletal dysplasia persists and may progress. Short stature[117,118] and the need for multiple orthopedic procedures are anticipated in transplanted individuals.[119,120,121] Odontoid dysplasia may improve after HSCT.[122] A role for additional ERT in well-engrafted individuals has not been defined.

Laronidase, recombinant α-L-iduronidase, was FDA approved in 2003 for the non-CNS manifestations of MPS I. Treated individuals, who require intravenous infusions weekly or biweekly, exhibit improvement in hepatosplenomegaly, joint range of motion, exercise tolerance, and biochemical markers (e.g., GAG excretion).[123] Intrathecal enzyme therapy has been used to a limited extent for spinal complications. A trial of intrathecal enzyme during the peritransplant period is ongoing. Although intravenous ERT may have a palliative role for individuals with MPS I H, who are not candidates for HSCT, early HSCT is superior.

Gene therapy efforts using adeno-associated virus (AAV) vectors transducing human cDNA for *IDUA* have shown restoration of enzyme activity in brain, but no human gene therapy trials have been reported.[124]

Small molecule approaches to restoration of endogenous activity have shown that GAG storage can be reduced in mice carrying a W392X mutation[57] on treatment with NB84, an aminoglycoside designed to suppress translation termination at in-frame premature termination codons. In human fibroblasts in vitro, chloramphenicol, a peptidyl transferase inhibitor, has been shown to increase α-L-iduronidase activity by 100-fold, but the mechanism appears to be different from stop codon readthrough.[125] There are currently no human trials of either of these approaches.

Mucopolysaccharidosis Type II (Hunter Syndrome)

Hunter syndrome is an X-linked recessive disorder resulting from a deficiency of iduronate-2-sulfatase. Boys with the severe variant may resemble children with the more severe variants of MPS I, although they typically present somewhat later. Many boys with Hunter disease are tall during infancy with coarse facial features, progressive evolution of developmental delay and eventual regression of milestones, stiff joints, clawhand deformity, hearing loss, and hepatosplenomegaly. Corneal clouding is absent. Behavioral difficulties, including aggression and disrupted sleep patterns, can be challenging. Diarrhea is a frequent complaint and can be difficult to manage. A specific skin feature is "peau d'orange," a white pebbly lesion often located on the back or upper arms. Boys with the "milder" form, who do not have cognitive involvement, may present with similar somatic features and progressively develop joint stiffness, carpal tunnel syndrome, and cardiac valve disease. The less severe form is compatible with survival into adulthood and with normal cognitive achievement. However, it is by no means clinically "mild."

The diagnosis may be first suspected on the basis of family history, clinical features, or abnormal radiologic findings. Quantitation and characterization of urine GAG excretion may be similar to findings in MPS I, and biochemical features do not predict clinical severity. Iduronate-2-sulfatase is present in plasma but can also be assayed in WBCs and cultured skin cells. Molecular confirmation is readily available, and hundreds of mutations of all types have been described. When clinical and biochemical evidence supports a diagnosis but sequencing fails to reveal a mutation, a deletion, which can involve contiguous genes, should be sought. In this case, an alternate diagnosis, such as multiple sulfatase (discussed later) deficiency, should be considered. Hunter syndrome is X-linked, and knowledge of the molecular lesion is important for genetic counseling in females at risk. Prenatal diagnosis is possible, and molecular analysis should be used as an adjunct to assays.

Treatment. HSCT has been disappointing in MPS II, although the reason for the difference in cognitive response to HSCT (as compared to MPS I) is unclear.[126] ERT with idursulfase was approved in 2006 to treat the non-CNS manifestations of MPS II, based on clinical endpoints of improved 6-minute walk and improved respiratory status.[127] The therapy involves weekly intravenous infusions and requires a significant family commitment to therapy. Regular infusions have been transferred to the home setting after demonstration of safety during the first several months.[128] Idursulfase does not enter the CNS, and ERT is not expected to have a significant impact on cognitive decline in severely affected boys. A clinical trial using the combination of intravenous and intrathecal enzyme is in progress. Gene therapy using AAV vectors has been studied in MPS II mice, with encouraging clearance of GAG is tissues and correction of skeletal abnormalities.[129,130] No human gene therapy trials are in progress.

Mucopolysaccharidosis Type III (Sanfilippo Syndrome)

MPS III has predominantly CNS manifestations and can be very difficult to diagnose during the toddler years. Before age 5 the mildly coarse features can be subtle, and the striking physical findings that make MPS I and II recognizable are absent (Fig. 25-9). There are four different enzymes implicated in this clinical phenotype, all of which lead to storage and urinary excretion of excessive heparan sulfate. In addition, glycosphingolipids accumulate in MPS III CNS. Phenotypic features include delayed language acquisition, hyperactivity, aggressive behavior, sleep disorders, and hirsutism. Loss of established milestones becomes evident at approximately 4 to 6 years. In general, individuals with MPS III A exhibit more rapid decline, and individuals with MPS III B have a less rapid course. The frequency of MPS III is approximately 1 in 100,000 in Western Europe, based on incidence of known cases, but many authorities suspect that MPS III may be significantly underdiagnosed.[131]

MPS III can be difficult to diagnose biochemically. Urine GAGs may be only mildly abnormal when analyzed at the quantitative level, and detection of the abnormal heparan sulfate requires characterization by electrophoresis or thin layer chromatography.[132] Only one of the enzymes, MPS III B (α-*N*-acetylglucosaminidase) can be assessed in circulating cells; the others require a skin fibroblast culture. Molecular analysis is available for all four variants and is required for accurate carrier assessment. Prenatal diagnosis is available using enzymatic analysis of cultured cells, augmented with molecular analysis.

Treatment. HSCT has been explored but does not appear to be effective, as murine models suggested.[133] Because the primary target for therapy for MPS III is the CNS, enzyme therapy trials have focused on intrathecal administration, and clinical trials are under way for MPS IIIA. Gene therapy has been attempted in MPS III B mice.[134] Genistein, which is a soy derivative widely available as a nutritional supplement, has provoked significant interest among MPS III families. Genistein decreased heparan sulfate in mouse brains[135] and decreased GAG excretion in human trials, but without a change in behavior.[136] Finally, some improvement with aspirin administration suggests that antiinflammatory drugs may play a role in altering the progressive CNS lesions of MPS III.[137]

Mucopolysaccharidosis Type IV (Morquio Syndrome)

MPS IV, a lysosomal disorder, is primarily a skeletal dysplasia without CNS disease.[138] Two different enzymes are implicated in MPS IV: MPS IV A is a deficiency of *N*-acetylgalactosemia-6-sulfatase, whereas MPS IV B is caused by deficiency of acid β-galactosidase. In both variants the degradation of keratan sulfate is impaired, and excessive keratan sulfate can be observed in urine. There is a continuum of severities, based on the age at which skeletal deformities appear. MPS IVA may present with hydrops, but hydrops and less severe presentations are found in the same family. Children with MPS IV have a short neck and trunk, prominent sternum, and kyphosis. They tend to waddle and are distinct from other individuals with MPS in that they have hypermobile joints rather than contractures. Valvular heart disease and restrictive pulmonary disease develop with age. Cognitive development is normal.

MPS IVB is biochemically interesting because it is allelic to GM_1 gangliosidosis. Some mutations affect the catabolism of both GM_1 ganglioside and keratan sulfate, resulting in a phenotype overlapping that of MPS IV B and GM_1 gangliosidosis, encompassing both neurologic and skeletal manifestations. Other mutations lead to phenocopies of MPS IVA.

Treatment. *N*-acetylgalactosamine-6-sulfatase, the MPS IV A enzyme, has been produced in therapeutic quantities in Chinese hamster ovary cells. Systemic administration to MPS IVA mice showed uptake and GAG reduction in chondrocytes.[139] Initial clinical trials in humans have shown improvement in 6-minute walk test and some pulmonary functions. A phase III trial is under way.

Mucopolysaccharidosis Type VI (Maroteaux-Lamy Syndrome)

MPS VI is an early onset pleiotropic disorder involving joint stiffness and contractures, short stature, coarse

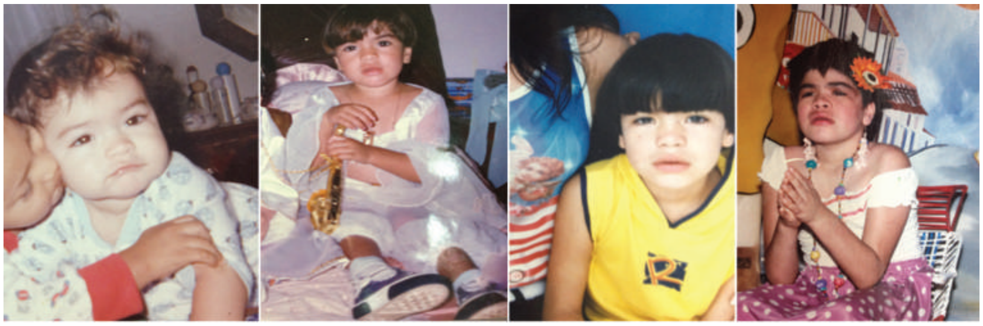

Figure 25-9 Sanfilippo disease progression of the facial phenotype. The mild coarseness of the facial dysmorphia can obscure the diagnosis early in the disease. The facial features become progressively more coarse but are still milder than in mucopolysaccharidosis I or II. *mo,* Months old; *yo,* years old.

facies, corneal clouding, and hearing loss. MPS VI can be confused with MPS I H and its attenuated variants. However, the CNS is not directly involved, and cognitive status is preserved, although some individuals require shunting because of hydrocephalus. Cardiac valve disease is common. Thickening of the dura may result in nerve impingement and myelopathy.[140] There is a spectrum of severities, and more mildly affected individuals may be underdiagnosed. MPS VI appears to be more common, albeit very rare, in South America, but overall prevalence is not known with accuracy.

Arylsulfatase B (ASB, galactosamine-4-sulfatase) is deficient in MPS VI and leads to an accumulation and excessive excretion of dermatan sulfate only, which provides a clue to the enzyme diagnosis. Measurement of ASB should be supplemented by assays of at least one other sulfatase enzyme to exclude multiple sulfatase deficiency, or molecular confirmation should be performed.[141]

Proof of the principle that MPS VI could be treated by cell transfer of enzyme was provided by earlier descriptions of improved joint mobility after HSCT.[142] ERT with galsulfatase was approved in 2006 by the FDA and EMA after clinical trials showed improved joint mobility and improved quality of life.[143]

Mucopolysaccharidosis VII (Sly Syndrome)

MPS VII, or β-glucuronidase deficiency, was initially described in 1973. Although the original patient had a rather stereotypical MPS course, with cognitive decline, organomegaly, short stature, and valvular heart disease, fetal presentation with hydrops may be the most frequent clinical variant.[144] This disorder has been studied extensively in murine models, and treatment efforts with enzyme therapy, HSCT, and gene therapy have showed variable outcomes.[145] ERT for MPS VII has been granted orphan drug status in the United States, and clinical trials are anticipated in this very rare disease.

Multiple Sulfatase Deficiency

Multiple sulfatase deficiency results from the failure of posttranslational conversion of a cysteine to 2-amino-3-oxopropionic acid (α–formylglycine), a modification required for activation of all members of the sulfatase family, which include nonlysosomal enzymes such as steroid sulfatase. The mutated gene, *SUMF-1*, encodes sulfatase-modifying factor 1. The clinical phenotype combines somatic features of all the MPS diseases owing to sulfatase deficiencies (coarse features, stiff joints, hearing loss, hepatomegaly) with those of metachromatic leukodystrophy (deficient arylsulfatase A). Ichthyosis caused by steroid sulfatase deficiency may be present. As with many lysosomal disorders, there is a spectrum of severities. Correct identification of multiple sulfatase deficiency is important to avoid inappropriate therapy with a single sulfatase replacement enzyme (idursulfase or galsulfase).[141] Development of an appropriate treatment strategy is challenging because many of the sulfatases are active in brain, are nonlysosomal, and have poorly defined functions.

Mucolipidosis Type II/ III (I-Cell Disease and Pseudo-Hurler Polydystrophy)

Mucolipidosis types II and III are allelic disorders in which internalization of lysosomal hydrolases by way of the M6P recognition marker is defective. The deficient enzyme, UDP-N-acetylglucosamine: lysosomal–enzyme N-acetylglucoseamin-1-phosphotransferase (GNPT), is encoded by *GNPTAB*. The more severe form, I-cell disease, may present with hydrops fetalis, short femurs, and intrauterine growth retardation. Coarse features may be noted in the neonatal period, and gingival hyperplasia is prominent. Growth retardation and developmental delay are usually noted earlier than in individuals with severe MPS I. The attenuated form, mucolipidosis type III, typically presents in early childhood with joint stiffness, contractures, and cardiac valve disease. Dysostosis multiplex may be noted on x-rays, but lack of excessive GAG excretion in urine provides a clue that the individual does not have MPS I, II, or VI. The assay of lysosomal enzymes in plasma show large increases in activity (e.g. 10- to 20-fold increases in β-hexosaminidases, iduronate sulfatase, and arylsulfatase A. Assays of such enzyme activities in the cell pellet of cultured cells or isolated WBCs show major deficiencies. In contrast, the plasma or cell culture media have high enzyme activities because the soluble lysosomal enzymes are secreted out of cells. Molecular confirmation through gene sequencing of *GNPTAB* is helpful for carrier determination and prenatal diagnosis. HSCT has been attempted in severe cases of I-cell disease, with some improvement in somatic features but no improvement in CNS status.[146]

Lysosomal Acid Lipase Deficiencies

Wolman disease and cholesteryl ester storage disease (CESD) are caused by defects of lysosomal acid lipase (LAL) and represent a continuum of disease. These conditions result from allelic mutations in *LIPA,* which maps to human chromosome 10q23.2–q23.3. The gene spans 45 kb and has 10 exons. LAL is essential to the degradation of cholesteryl esters and triglycerides that are delivered to the lysosome by LDL or other receptor-mediated endocytosis. LAL cleaves the fatty acids from these substrates to produce free cholesterol and fatty acids. Subsequent to LAL cleavage, cholesterol and free fatty acids exit the lysosome, enter the cytosol, and participate in the complex SREBP systems to modulate intracellular cholesterol and fatty acid synthesis.[147] In LAL deficiency, cholesteryl esters and triglycerides cannot be cleaved and their egress from the lysosome is blocked.[148] Cells sense this as cytoplasmic cholesterol and free fatty acid deficiencies with resultant upregulation of these biosynthetic pathways. LAL is ubiquitously expressed and is particularly abundant in macrophages, fibroblasts, lymphocytes, and hepatocytes. Although LAL is expressed in cells of the CNS, there seems to be no major role for this enzyme in cholesterol metabolism in the brain. A major difference between Wolman disease and CESD is the absence or presence, respectively, of small amounts of normal LAL in cells. A common *LIPA* splice junction mutation in

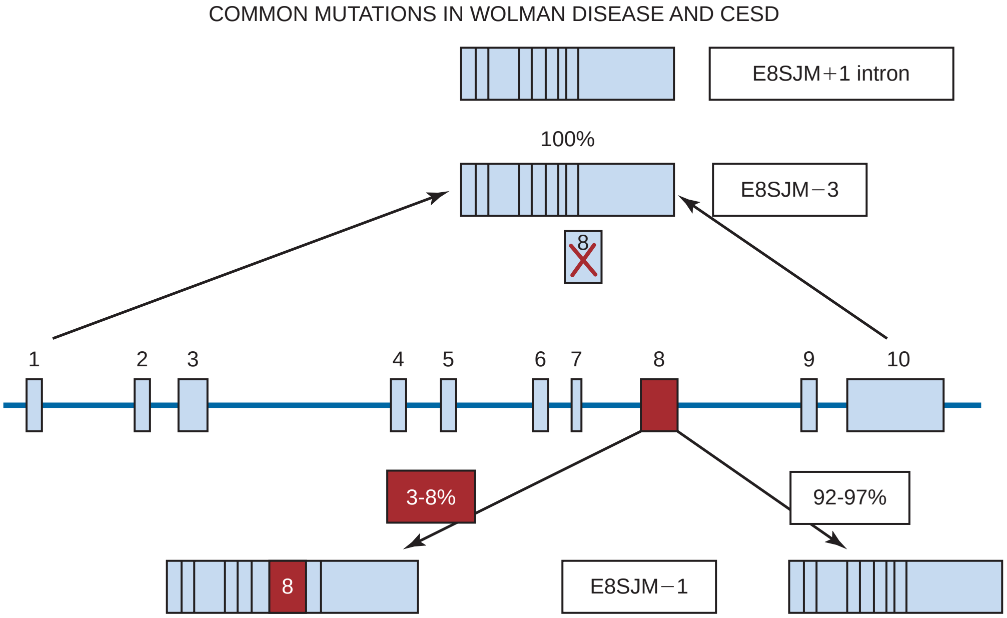

Figure 25-10 Lysosomal acid lipase (LAL) gene and splicing mutations. *LIPA* structure *(middle)* with 10 exons. Above *LIPA* are shown two different Wolman disease splice junction mutations that lead to the production of mutant LAL protein missing exon 8. Below *LIPA* is the common E8SJM-1 mutation in cholesteryl ester storage disease that leads to ~3% to 8% of normal LAL mRNA and protein being produced, whereas 92% to 97% of the LAL transcript is missing exon 8. Also, two nondeleterious mutations have been found in this same region.

CESD leads to production of about 3% to 8% of normal LAL mRNA and protein. This and the preferential cleavage of triglycerides, compared with cholesteryl esters, by LAL may account for the differences between Wolman disease and CESD (Fig. 25-10).

Wolman Disease

Wolman disease is a severe infantile disease with a mean age of death of approximately 3.5 months. It has a frequency of approximately 1 in 300,000 to 1 in 500,000 live births, but better ascertainment is needed.[149] The major clinical manifestations of severe vomiting, failure to thrive, abdominal distention, and massive hepatosplenomegaly have been reported in patients as young as 4 days of age.[150] Jaundice or persistent low-grade fever develops in a few infants. A prominent feature in about 60% of such patients is symmetrically enlarged, calcified adrenal glands.[151] Radiographic examination demonstrates extensive, stippled, or punctuate calcific deposits.

By the sixth week, progressive anemia usually develops. Peripheral blood lymphocytes contain both intracytoplasmic and intranuclear lipid vacuoles. In contrast to other diseases characterized by vacuolated cells, the vacuoles in Wolman disease are strongly sudanophilic and stain positively with oil red O, Nile red, and filipin for cholesterol. Their lysosomal origin is indicated by a strong reaction to staining for acid phosphatase activity. Lipid droplets may be present in neutrophils and monocytes. Foam cells (lipid-laden macrophages) are present in the bone marrow, the peripheral blood, and all organs.[150] Thrombocytopenia is not seen. Acanthocytosis has been reported.[152]

Vomiting, diarrhea, and inanition result from severe damage to the intestinal microvilli and the accumulation of foam cells in the intestinal mucosa. Abdominal ultrasonography may demonstrate thickened bowel walls.[153] Eventually, attempts to provide enteral nutrition may be futile, and intravenous hyperalimentation may be initiated as a palliative measure.[154] The disease progresses rapidly, and death usually occurs before 1 year.

The diagnosis is suspected by the clinical findings and deficient activity of LAL in cultured fibroblasts or circulating leukocytes. No specific blood chemical abnormalities are present in patients with Wolman disease. Hypercholesterolemia is not a feature, probably owing to malabsorption. Insufficient glucocorticoid response to adrenocorticotropic hormone (ACTH) may be observed; when present, this indicates the need for glucocorticoid supplementation.[155]

Cholesteryl Ester Storage Disease

CESD has a variable phenotype that ranges from severe progressive liver fibrosis and cirrhosis with hypercholesterolemia to a nonalcoholic fatty liver disease (NAFLD) phenotype that may remain undetected until adulthood.[156] Because of this variability the true prevalence of CESD is unknown. Based on DNA testing, approximately 1 in 40,000 and 1 in 70,000 are predicted to have CESD in Germany and Czech Republic, respectively. Among a selected group of patients with heart disease in the United States, molecular analyses indicated a prevalence of about 1 in 160,000 in Caucasians.[157] Greater suspicion in patients with NAFLD and hyperlipidemia may allow refinement of the true prevalence and phenotypic spectrum. Hepatomegaly, a prominent sign, may be evident at birth, during early childhood, or occasionally in the second decade of life. It results from the fatty infiltration of foam cells, progressive hepatocellular lipid accumulation, and ultimately hepatic fibrosis and cirrhosis. About 25% of children with CESD experience liver failure and have hepatic transplantation. Alcohol has been known to accelerate the process and therefore should be avoided. Other clinical features include recurrent abdominal pain, delayed puberty, recurrent epistaxis, jaundice, splenomegaly, esophageal varices, and decreased concentration of blood clotting factor V. Calcified adrenal glands are rarely seen. Malabsorption and malnutrition have not been described in patients with CESD. It is important to note that the CNS is not involved in CESD.

Plasma levels of cholesterol, triglyceride, and low-density lipoproteins are elevated, and the plasma high-density lipoprotein concentration is reduced. Isolated hypercholesterolemia may be the sole clinical finding in children and adults, and routine chemistry profiles may be completely normal. Lymphocytes and monocytes are the only blood cells affected in CESD. Bone marrow aspirates may demonstrate large macrophages filled with birefringent droplets. Cultured skin fibroblasts of patients with CESD demonstrate birefringence in plain polarized light. Sharply reduced lysosomal acid lipase activity in the lymphocytes or culture fibroblasts establishes the diagnosis. Liver LAL activity is reduced but detectable and is substantially greater than such activity in the liver of patients with Wolman disease.[158]

Treatment. In some patients treatment with 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (lovastatin or simvastatin) and with lipophilic vitamins (A, D, E, and K) has resulted in significant reductions in plasma cholesterol, triglyceride, and low-density lipoprotein cholesterol levels, without changing the progression of hepatic disease.[159] Several patients with CESD have received liver transplants with variable results.[160-162]

A null-mutant murine model of LAL appeared normal at birth and developed normally into adulthood. However, massive accumulation of triglycerides and cholesteryl esters (30-fold increase in comparison to normal) occurred in several organs, and at 3 weeks of age the liver appeared yellow-orange and up to two times larger than normal. This murine model is a phenocopy of CESD and a biochemical and histopathologic mimic of human Wolman disease.[163] ERT with recombinant LAL resulted in nearly complete resolution of the hepatic yellow color and a decrease in hepatic weight. Histologic analysis of tissues from ERT-treated mice showed a reduction in macrophage lipid storage and a 50% to 70% decrease in triglyceride and cholesterol levels in the liver, spleen, and small intestine.[164,165] ERT with recombinant enzyme for human LAL deficiencies are currently under evaluation (http://clinicaltrials.gov).[166]

HSCT has been attempted in a few children with Wolman disease. Although long-term survival was reported in one case, generally the patients do not survive.[167] The neurologic performance of the one surviving patient, who received a transplant at 5 months of age, has been good, as would be expected insofar as LAL appears to have no significant role in CNS lipid metabolism.

Neuronal Ceroid Lipofuscinoses

Lysosomal accumulation of lipopigments is characteristic of the neuronal ceroid lipofuscinoses, a group of neurodegenerative conditions whose biochemical bases have only recently begun to be understood. The stored material consists of autofluorescent lipopigments resembling lipofuscin, the material that accumulates in neurons in normal aging. However, the storage material related to neuronal ceroid lipofuscinoses is less sharply outlined and more faintly stained by aldehyde fuchsin than the normal lipofuscin deposits.[168] The neuronal ceroid lipofuscinoses genes encode soluble and transmembrane proteins, localized to the ER or the endosomal or lysosomal organelles. The precise function of most of the neuronal ceroid lipofuscinoses proteins and their cellular dysfunction remains unclear.

The accumulations present in brain lysosomes include glycoconjugates consisting primarily of dolichol pyrophosphate-linked oligosaccharides and proteins, the major component being subunit c (unit 9) of mitochondrial adenosine triphosphate (ATP) synthase. By immunohistochemistry, this excess of subunit c can be identified in skin fibroblasts[169] and in urine.[170,171] On electron microscopy the residual bodies have a heterogeneous appearance. They are present in all tissues but are particularly abundant in the neuronal perikaryon and axon hillock, where they continue to accumulate until the nerve cell degenerates. Neuronal ceroid lipofuscinoses exert a profound effect on the CNS of affected individuals by their progressive nature, leading to blindness, neurocognitive decline, intractable seizures, and ultimately premature death.[172-174] It is not clear why these conditions involve the CNS almost exclusively because the proteins affected are also found in many extraneural tissues.[175]

The neuronal ceroid lipofuscinoses represent a broad spectrum of diseases with an overall incidence of approximately 1 in 12,500 to 25,000 births.[173] The neuronal ceroid lipofuscinoses are probably the most common group of hereditary progressive encephalopathies in children.[173] The age at onset; visual, mental, and motor signs; and types of inclusions present vary in the different forms of the disease. At least eight major forms of the disease have been identified (Table 25-2). These forms show a consistent clinical, pathologic, and genetic picture.[176] The classic forms are infantile (CLN-1), late infantile (CLN-2), and juvenile (CLN-3) neuronal ceroid lipofuscinosis. These forms are inherited in an autosomal recessive pattern and have different genetic bases. An adult onset variant without vision loss (CLN-4) also occurs. Most patients demonstrate autosomal recessive inheritance, but an autosomal dominant pattern has also been found in a few patients. Four additional variants (Finnish, or type 5; Gypsy/Indian, or type 6; Turkish, or type 7; and northern epilepsy with mental retardation, or type 8) have thus far been restricted to specific ethnic groups.[177] Their phenotypes resemble that for type 2, and their genetic bases have been identified. In neuronal ceroid lipofuscinosis

TABLE 25-2 Phenotypic/Genotypic Correlations of Neuronal Ceroid Lipofuscinoses

Form	Genetic Symbol	Onset, Range (yr)	Initial Symptoms	EM	Enzyme Activity Assay	Gene Symbol	OMIM	DNA Testing (Common Mutation)

type 8, missense mutations have been found in most affected patients.

Children with CLN-1 are normal at birth. Symptoms usually present acutely between ages 6 and 24 months. Initial symptoms include delayed development, myoclonic jerks, seizures, and deceleration of head growth. Affected infants develop retinal blindness and seizures by 2 years of age, followed by progressive intellectual disability.[178,179] The first symptoms of CLN-2 typically appear between 2 and 4 years, usually starting with epilepsy, followed by regression of developmental milestones, dementia, ataxia, and extrapyramidal and pyramidal signs. Visual impairment typically appears at age 4 to 6 and rapidly progresses to blindness. Life expectancy ranges from 6 to older than 40 years.[172,180] The onset of CLN-3 is usually between 4 and 10 years. Rapidly progressive visual loss resulting in total blindness within 2 to 4 years is often the first clinical sign. Epilepsy with generalized tonic-clonic seizures, complex-partial seizures, or myoclonic seizures typically appears between 5 and 18 years. Life expectancy ranges from the late teens to the 30s.[181-183] Initial signs and symptoms of CLN-4 usually appear at approximately age 30, with death occurring about 10 years later. Affected individuals exhibit either progressive myoclonic epilepsy or behavior abnormalities, and all have dementia, ataxia, and late-occurring pyramidal and extrapyramidal signs.[184] Northern epilepsy, or progressive epilepsy with mental retardation (EPMR) is predominant in Finland and is characterized by tonic-clonic or complex-partial seizures, intellectual disability, and motor dysfunction. Onset occurs between 2 and 10 years.[185]

With only rare exceptions, patients who show signs before adulthood become blind, and for this reason older texts usually grouped these diseases among the familial amaurotic disorders. However, the absence of ganglioside storage and the marked brain atrophy that occur in the neuronal ceroid lipofuscinoses clearly set these diseases apart from the classic forms of gangliosidoses (i.e., Tay-Sachs disease, Sandhoff disease, and the GM$_1$ gangliosidoses). Seizures, another common sign in neuronal ceroid lipofuscinoses, may be related to selective loss of inhibitory synapses within the axon hillock and initial segment of pyramidal cells. Their presence may lead to confusion with other causes of progressive myoclonic epilepsy, including Unverricht-Lundborg disease, myoclonic epilepsy with ragged-red fibers, Lafora disease, and the sialidoses. In contrast to these other disorders, each variant of the neuronal ceroid lipofuscinoses is associated with the accumulation of autofluorescent material.

Retinal degeneration can be monitored with electroretinography. With complete degeneration of the outer retinal layer, the electroretinographic response is totally abolished. Another useful test is electroencephalography, the results of which may be abnormal even before the development of dementia. Computed tomography and magnetic resonance imaging have been useful to document loss of gray matter early in the course of infantile neuronal ceroid lipofuscinosis.[186]

Diagnosis of these relatively common disorders depends primarily on the clinical features, but examination of a skin biopsy specimen by electron microscopy also helps greatly. Lymphocyte vacuolization and azurophilic hypergranulation of neutrophils are often found in the peripheral blood smear, except in the infantile form of the disease. Electron microscopic studies of these blood elements and urinary sediment, conjunctiva, liver, skeletal muscle, and sural nerve have also aided in the diagnosis. In juvenile neuronal ceroid lipofuscinosis, fingerprint lipopigments may appear on electron micrographs of lymphocytes in the absence of vacuoles. More recently, molecular diagnosis has become clinically available for the majority of the neuronal ceroid lipofuscinoses, making the diagnosis less invasive.

Clinical, pathologic, and biochemical changes similar to those seen in humans with neuronal ceroid lipofuscinosis have been detected in several animal species.[187-190] These naturally occurring animal models provide important clues regarding the pathogenesis of neuronal ceroid lipofuscinoses and offer investigators the opportunity to study potential treatments of these disorders. HSCT and liver transplantation in English setter dogs did not lead to CNS stabilization or improvement, nor have treatments with vitamin E, selenium, levodopa, or glutathione or peroxidase enzyme. Addition of 20% corn starch to their diet did improve the quality of life but failed to alter disease progression[189]

The only treatment currently available is symptomatic. Baclofen (15 to 25 mg/day, increasing to as much as 200 mg/day) and tizanidine (1 to 9 mg/day, later 20 to 60 mg/day) have been helpful for controlling irritability, choreoathetosis, and sleep disturbances. Levomepromazine (5 to 20 mg/day) or benzodiazepines may also be beneficial.[191] Cysteamine bitartrate reduces storage material in CLN1-deficient cells. An open-label 7-year trial in CLN1-affected children failed to show overall attenuation of disease progression.[192] Moreover, HSCT is not therapeutic.

Krabbe Disease

Krabbe disease results from mutations in *GALC*, which encodes galactocerebrosidase. This enzyme uniquely degrades galactosylsphingosine, a deacylated analogue of galactosylceramide. Sulfatide and galactocerebroside are important constituents of myelin that are synthetized by oligodendrocytes and Schwann cells. Galactosylsphingosine is highly toxic to several cell types in the CNS, particularly oligodendrocytes and Schwann cells.[193] The Krabbe disease phenotype matches well with the primary involvement of these cells and secondary neuroinflammatory responses. The majority of affected individuals have infantile Krabbe disease with onset before 6 months. The later forms of Krabbe disease have a variable life expectancy and presentation but are collectively called *late onset Krabbe disease*.[194] A birth frequency of approximately 1 in 100,000 is generally given, but the results from the New York State Newborn Screening Program indicate a frequency of 1 in 275,000.[195] The carrier frequency of these panethnic diseases in individuals with no family history is approximately 1 in 150.

Infantile Krabbe Disease

Infantile Krabbe disease is divided into four stages: stage I—irritability, vomiting, and feeding problems (gastroesophageal reflux); stage II—muscular hypertonia of limbs, pyramidal signs, and difficulty feeding; stage III—hypertonia in all limbs and opisthotonic posturing followed by progressive depression of deep tendon reflexes, reflecting a polyneuropathy (optic atrophy and sluggish pupillary reactions to light are common); stage IV—"burned out stage" with immobility, either hypotonic or decerebrate, and inability to feed, jerky eye movements, seizures, unexplained fevers, and startle reflexes. These are general stages, and not all patients fit them chronologically. Malnutrition and global CNS atrophy lead to decreased head circumference. Average survival is 2 years or less.

Abnormal neurophysiologic studies are present early in infantile Krabbe disease with reduced nerve conduction studies before the appearance of specific signs.[196] Also, visual evoked potentials (VEPs) and brainstem auditory evoked responses (BAER) are abnormal early in patients with infantile Krabbe disease.[196] Peripheral neuropathy is observed in approximately 50% of patients with late onset Krabbe disease, and nerve conduction velocity (NCV) studies can be normal in some affected adults.[197] MRI signal abnormalities occur within cerebellar white matter, the deep gray nuclei, and the pyramidal tracts. Involvement of the parietooccipital white matter and corpus callosum develop rapidly and simultaneously with global atrophy.[198]

Late Onset Krabbe disease

Late onset Krabbe disease includes two forms: late infantile, with onset after 6 months to age 3, and juvenile Krabbe disease, with onset by 3 to 8 years of age. Survival correlates with age of onset, with death occurring approximately 2 years after onset for the late infantile and more than 7 years after onset for the juvenile form.[196] Late onset Krabbe disease has three main signs: motor weakness, vision loss, and intellectual regression. Progressive equinovarus, with walking difficulties, in a previously normal or mildly delayed child, may appear first. A spastic paraparesis supervenes, sometimes associated with cerebellar ataxia and dystonia. Visual failure caused by optic atrophy is almost universal with advancing age. In many cases dementia progresses after the onset of motor signs.[197] This classical progression is not present in all cases.[199] In late onset Krabbe disease, MRI reveals abnormalities in the pyramidal tracts, posterior corpus callosum, and parietooccipital white matter.[199] Hypertrophy of the optic nerves, optic chiasm, and other cranial nerves can be present, as can radial stripes inside demyelinated tracts.[200,201]

Treatment

Supportive care to control irritability and spasticity in children with infantile onset Krabbe disease is the only management available in the later stages of the disease. HSCT has been performed in patients of all ages with variable success.[202,203] HSCT in newborns with infantile Krabbe disease prolongs survival; cognitive decline is greatly slowed and peripheral nervous system function may deteriorate, but these depend on the time at which transplant was performed.[204] There are no consensus criteria for HSCT in Krabbe disease. Disease stages (I to IV) have been used to guide candidacy for HSCT.[205] Outcome analysis has demonstrated that patients with minimal to no disease progression at time of HSCT (stages I or II) have good survival after HSCT and progress in their development, whereas patients with more advanced disease (stages III or IV) have significantly higher mortality after HSCT with no developmental improvement. A multicenter study of 16 infants with Krabbe disease after HSCT in the early disease stage, who were mostly ascertained by family history, showed that all developed abnormalities of gross motor control and expressive language.[204] Receptive language and cognition were considered normal in this cohort, although assessments can be difficult in children with motor and expressive language deficits. These patients also had poor growth and developed spasticity, loss of motor milestones, and microcephaly. These studies suggest that HSCT should be performed in this age group only when symptoms are absent or mild, but despite transplantation there will be significant neurologic morbidity.[205]

Identification of Krabbe disease by newborn screening facilitates the initiation of treatment before neurologic damage ensues. The decision to treat and the time to start therapy are challenging in Krabbe disease because HSCT carries significant morbidity and mortality risks. Acute or chronic graft-versus-host disease has been reported in up to 32% of transplanted patients.[203,206] Prediction of clinical course with and without treatment is limited, as is the current understanding of genotype-phenotype correlation. The significant clinical variability in late onset forms (even those with the same genotype) makes evaluation of treatment effectiveness difficult.

Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD) is caused by mutations in *ARSA*, which encodes arylsulfatase A (ASA). Three clinical subtypes characterize MLD: late infantile MLD (50% to 60% of cases), juvenile MLD (20% to 30% of cases), and adult MLD (15% to 20% of cases).[207] Age of onset within a family is usually consistent. The prevalence of MLD has been reported to be between 1 in 40,000 to 1 in 160,000 in different populations. The carrier frequency is approximately 1 in 100 to 1 in 200. MLD was the most common diagnosis among children in Utah with inherited leukodystrophy.[208]

MLD is suspected in individuals with progressive neurologic dysfunction and MRI evidence of a leukodystrophy. MLD is suggested by ASA enzyme activity in leukocytes that is less than 10% of normal controls; however, assay of ASA activity cannot distinguish between MLD and *ARSA* pseudodeficiency, in which ASA activity is 5% to 20% of normal and MLD fails to ensue. The diagnosis of MLD must be confirmed by molecular genetic testing and urinary excretion of sulfatides.

Late-infantile MLD is characterized by onset by 1 to 2 years in a child with previously normal development. Typical initial findings are weakness, hypotonia, frequent falls, toe walking, and slurred speech. Later signs include inability to stand, poor speech, cognitive decline, hypertonia, pain, seizures, vision and hearing impairment, and peripheral neuropathy. In the final stages, children have spasms and decerebrate posturing and are no longer aware of their surroundings.[209]

Juvenile MLD is characterized by onset between 4 years and sexual maturity. Typical presentation includes decline in school performance and behavioral problems, followed by gait abnormalities, slurred speech, and incontinence. Seizures may occur. Progression is slower than the late-infantile form. Survival for 10 to 20 or more years after the initial diagnosis is common.

Adult MLD is characterized by onset after sexual maturity until the fourth or fifth decade. Initial manifestations are problems in school or job performance, personality changes, alcohol or drug abuse, poor financial decisions, and emotional lability. In other patients neurologic symptoms predominate and include weakness and loss of coordination that progresses to spasticity and incontinence.[210] Peripheral neuropathy is common in this group. Disease course is variable and slow, with periods of stability and decline.

Treatment

MLD leads to progressive loss of function and continually changing clinical care needs. Symptomatic treatment includes management of seizures using antiepileptic medications, physical therapy to maintain joint mobility, and treatment of contractures with muscle relaxants. Aggressive therapies to preserve neuromuscular function, intellectual abilities, and mobility are a critical component of care for these patients. Family involvement is important to help anticipate decisions regarding wheelchairs, feeding tubes, suction equipment, and other care needs.

HSCT is the only potential therapy available for primary CNS manifestations in MLD.[211,212] Reduced-intensity conditioning accompanied by mesenchymal stromal cell infusion has been well tolerated in adult patients with MLD.[213] Single center experiences with HSCT have generally included a limited number of patients with MLD and with controversial outcomes. The best results are obtained when transplant is performed before signs and symptoms have developed and in the later onset forms of the disease. Poor clinical results of HSCT have been reported in symptomatic MLD patients.[214] HSCT slows CNS progression but does not prevent peripheral nervous system manifestations.[215] In an individual with juvenile MLD, there was less peripheral nervous system progression during the 2 years after HSCT, with stabilization of disease.[216] HSCT was performed in a presymptomatic neonate, and disease progression was not prevented.[217] HSCT carries a substantial risk, and long-term benefits in MLD need to be evaluated. Improvements in the effectiveness of HSCT have been attempted by incorporation of *ARSA* gene constructs into hematopoietic stem cells using lentiviral vectors.[218] After myeloablation, HSCT with the genetically modified cells led to reconstitution of the hematopoietic system and apparent nonprogression of the CNS disease.[218] This promising result likely results from repopulation of the CNS macrophages that secrete large amounts of ARSA for cross-correction of multiple affected cell types, as suggested by the high levels of CSF ARSA.

In comparison, ERT efficacy is limited in neuronopathic lysosomal diseases because of the blood-brain barrier. Phase I and phase II clinical trials of intravenous recombinant ARSA enzyme failed to show clinical improvement. Currently, ERT administered intrathecally is under evaluation (http://clinicaltrials.gov). Other research therapies include AAV vectors containing human ARSA administered into the brains of nonhuman primates. ASA was increased by 12% to 38% without adverse effects, suggesting that a similar approach could be feasible in MLD.[219]

CHAPTER 26

Platelets and the Vessel Wall

Peter J. Newman and **Debra K. Newman**

CHAPTER OUTLINE

PLATELET MORPHOLOGY AND SUBCELLULAR ORGANIZATION
PLATELET GENOMICS AND PROTEOMICS
ANTITHROMBOTIC COMPONENTS OF THE VESSEL WALL
REACTING TO THE BREACH: CELL SURFACE RECEPTORS THAT MEDIATE TETHERING AND ADHESION AND TRANSMIT EARLY ACTIVATION SIGNALS
PLATELET GRANULES AND THEIR ROLE IN HEMOSTASIS
FEED-FORWARD AMPLIFICATION PATHWAYS INVOLVED IN PLATELET RECRUITMENT AND THROMBUS STABILITY
ACTIVATION OF THE MAJOR PLATELET INTEGRIN, αIIbβ_3 (GPIIb-IIIa complex)—THE FINAL COMMON ENDPOINT OF PLATELET ACTIVATION
CELL SURFACE AND CYTOSOLIC PROTEINS THAT LIMIT PLATELET RESPONSIVENESS
NONHEMOSTATIC ROLES FOR PLATELETS: BLOOD VESSEL MAINTENANCE AND REPAIR, INFLAMMATION AND INFECTION, AND ATHEROTHROMBOSIS

In an 1881 communication to the Turin Royal Academy of Medicine, the Italian physician Giulio Bizzozero disclosed the presence in circulating human blood of discrete elements that he termed "*piastrine*" ("*Blutplättchen*" in a 1882 publication in a German journal and "*petites plaques*" in a communication in French).[1] Previously speculated to be merely nonphysiologic "granular aggregates," blood platelets have since become central to the understanding of thrombosis and hemostasis, and detailed understanding of their participation in cardiovascular disease, stroke, and even cancer has led to remarkable progress in the rational treatment of these disorders.

Although platelets are most often studied in the context of their ability to form a hemostatically effective plug, it is now widely recognized that their influence extends far beyond this process to all aspects of hemostasis, as well as to wound healing and vascular remodeling. For example, platelets generate or secrete biologically active mediators such as thromboxane A_2 (TXA_2) and serotonin, which not only amplify platelet activation responses but also modulate vascular tone. In addition, platelets secrete a broad array of granule constituents that stimulate vessel repair, induce megakaryocytopoiesis, promote coagulation, and limit fibrinolysis.

The same pathways that lead to platelet plug formation can also produce pathologic thrombosis, a process that has been described as hemostasis occurring at the wrong time or in the wrong place. Platelets are particularly important for hemostasis on the arterial side of the circulation, where blood flows under higher pressure and experiences greater shear force. As a result, platelet function is generally considered to be critical to the pathogenesis of arterial thrombosis and less so for venous thrombosis, and antiplatelet drugs are most widely used in the former setting. However, this distinction between the mechanisms underlying arterial and venous thrombosis is not absolute, and the spectrum of thrombotic disorders should be considered a continuum.

Arterial thrombosis is a particularly common problem in middle-aged and older adults and is a major cause of morbidity and mortality in developed countries. The thrombi that arise in atherosclerotic vessels are predominantly platelet in origin and are the proximate cause of myocardial infarction and most cerebrovascular accidents. Although arterial thrombosis is considerably less common in children than adults, it may contribute to major morbidity in patients with sickle cell disease, as well as complications of some childhood infections, Kawasaki syndrome, and various forms of arteritis, autoimmune disorders, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura (see Chapter 34).

In this chapter platelet structure and function are reviewed, and special emphasis is given to the cell surface glycoproteins (GPs) that function as sentries for areas of vascular damage and the signal transduction events that both amplify and limit platelet responsiveness. The information provided should be helpful in understanding subsequent chapters that describe inherited and acquired platelet disorders (see Chapters 30 and 34) and the role of the adhesive protein von Willebrand factor (VWF) in hemostasis (see Chapter 31). Finally, there is growing appreciation of the role that platelets play in inflammation and the pathogenesis of atherothrombosis, which is briefly discussed at the end of the chapter.

PLATELET MORPHOLOGY AND SUBCELLULAR ORGANIZATION

Platelets are adhesion and signaling machines that circulate as small, disc-shaped cellular fragments in the whole blood of healthy individuals at a concentration of approximately 150,000 to 300,000 per μL. Early studies suggested that platelets might be produced via cytoplasmic fragmentation along a network of internal demarcation membranes that were observed in large, polyploid megakaryocytes.[2,3] More recent studies,[4-6] however, support the notion that proplatelets are assembled and packaged with their various constituents at the ends of long cytoplasmic extensions of differentiated megakaryocytes that have migrated from the proliferative osteoblastic niche to the capillary-rich vascular niche of the bone marrow microenvironment,[7] with the invaginated demarcation membrane system serving simply as a reservoir of internal membrane used for proplatelet extension.[8,9] Once adjacent to the adluminal face of the endothelium, proplatelets are released into the blood stream,[10] where they circulate as mature platelets for approximately 7 to 10 days before being cleared by the liver and spleen,[11] their life span being controlled at least in part by an antagonistic balance between the apoptotic proteins Bcl-xL and Bak.[12]

The size of resting platelets is somewhat variable, averaging approximately 1.5 μm in diameter and 0.5 to 1 μm in thickness. Platelet size is undoubtedly regulated by numerous factors during their biogenesis, but both the 224-kDa nonmuscle myosin heavy chain IIA (MYHIIA) and the cell-surface glycoprotein Ib complex (GPIb) appear to play critical roles. Thus mutations in the *MYH9* gene act dominantly to interfere with contractile events important for platelet formation,[13] whereas failure to express GPIb results in Bernard-Soulier syndrome[14,15] by disruption of critical associations with the cytoskeletal protein filamin,[16,17] which play an essential role both in platelet formation and in platelet compliance.[18,19] In both of these inherited platelet disorders, platelets are as large as lymphocytes (see Chapter 30). Correction of GPIb expression in GP Ib-deficient (Bernard-Soulier syndrome) mice has been shown to restore platelets to their normal size.[20]

The volume of platelets (mean platelet volume) normally ranges from 6 to 10 femtoliters. Platelet density is also variable,[21] and the issue of whether young platelets are more[22,23] or less[24] dense as they gain versus lose content during their circulating lifetime has never been satisfactorily resolved. Because platelets retain most species of messenger ribonucleic acid (mRNA) for a short period after their release from bone marrow megakaryocytes,[25] young platelets can be distinguished from older ones based on their RNA content.[26]

As shown in Figure 26-1, *A* and *C*, resting platelets are discoid in shape, largely because of the presence of a circumferential coil of microtubules,[27,28] and are packed with numerous electron-opaque α granules, a few dense (δ) granules, several mitochondria, and lysosomes.[29] Platelets also retain a few Golgi bodies, as well as occasional vestiges of rough endoplasmic reticulum—the exception being platelets from patients with rapid platelet turnover, where very young platelets containing more abundant protein synthesis machinery are readily observed in the circulation. Platelets also contain two highly specialized membrane systems not found in other cells of the body: the surface-connected open canalicular system (OCS; see Fig. 26-1, *B* and *C*), and the dense tubular system (DTS). The OCS is a series of tortuous invaginations of the plasma membrane that appear to tunnel throughout the cytoplasm of the cell[30] that serves as an internal reservoir of plasma membrane that is called upon when platelets round up, extend lamellipods and filopods (see Fig. 26-1, *B* and *D*), and spread during platelet activation—a process that can increase by more than 400% the surface area of exposed plasma membrane.[31] Because OCS channels are proximal to internal granules, they also likely function as a conduit for the rapid expulsion of α- and δ-granule contents during platelet activation.[32] The DTS, on the other hand, is a remnant of the smooth endoplasmic reticulum[33] and is found randomly dispersed throughout the cytoplasm. The DTS appears to be one of several organelles within the platelet known to harbor high concentrations of calcium[34,35] and is thought to contain a 100-kDa calcium adenosinetriphosphatase (ATPase) known as *sarcoplasmic/endoplasmic reticulum* Ca^{2+}*-ATPase 2b* (*SERCA2-b*)[36] that functions to sequester and store cytosolic calcium in resting cells. Recent evidence suggests that adenosine diphosphate (ADP) is able to induce selective release of calcium from the DTS,[37] whereas activation of the GPIb/V/IX receptor for VWF releases calcium primarily from a poorly defined acidic compartment within the cell.[38] Thrombin, a strong platelet agonist, appears to elicit calcium release from both stores upon binding to the platelet thrombin receptor PAR-1.[37]

The platelet cytoskeleton is comprised of a single, rigid but dynamic microtubule of approximately 100 μm in length coiled 8 to 12 times around the equatorial plane of the cell.[39-41] This marginal band of microtubules is largely responsible for maintaining the discoid shape of the resting cell, as illustrated by the observations that 1) incubation of platelets with colchicine, an agent that dissolves microtubules, results in their rounding[42]; 2) platelets from mice lacking β_1 tubulin remain largely spherical[43]; and 3) "platelet spherocytosis" in humans results when tubulin fails to polymerize normally into microtubules.[44] Directly underneath the plasma membrane lies an intricate, two-dimensional, tightly-woven

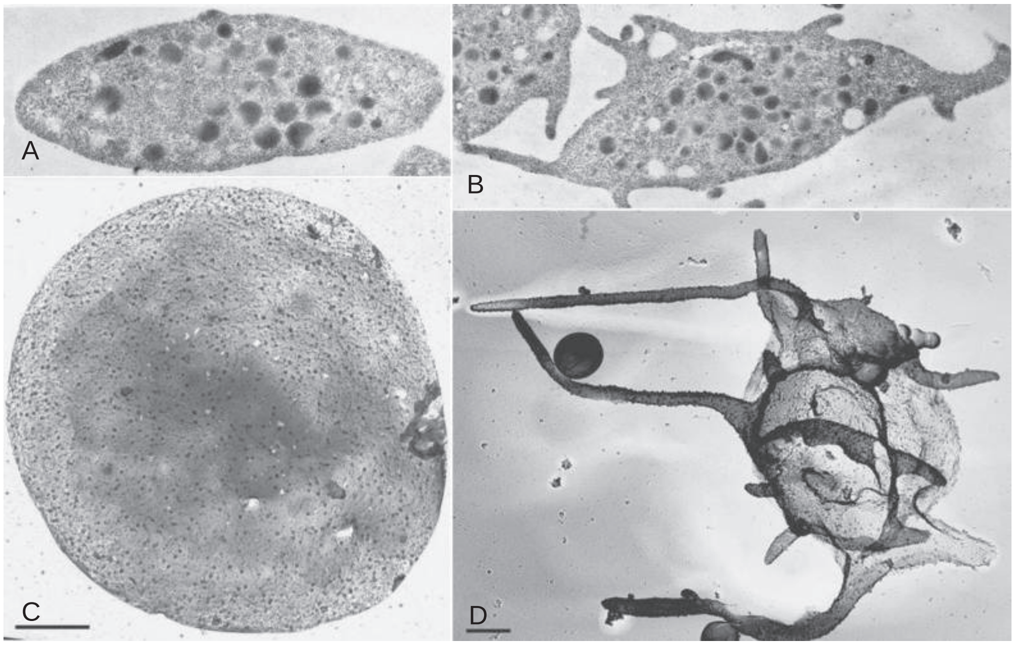

Figure 26-1 Platelet morphology. Resting platelets (**A**, thin section, and **C**, from a scanning electron micrograph of a flash-frozen, freeze-dried platelet) are shaped like a disc and contain numerous electron-opaque α granules, a few dense granules, and several mitochondria and lysosomes. A circumferential coil of microtubules is responsible for maintaining their discoid shape. Platelets also contain a number of cytoplasmic membrane systems that subserve specialized functions, including vestiges of the smooth endoplasmic reticulum that sequester calcium and tortuous invaginations of the plasma membrane that form a surface-connected open canalicular system (OCS). When platelets become activated (**B** and **D**), they rapidly round up, extend lamellipodia and filopodia, and release the contents of their granules, often into the nearby OCS. *(Courtesy of John H. Hartwig.)*

membrane skeleton[45] comprised of nonerythroid spectrin,[46,47] a network of actin filaments,[45,47] vinculin,[48] and the actin-binding protein filamin,[49] which itself is tethered to the inner face of the plasma membrane via linkages with the cytoplasmic domain of GPIb.[16,49] The membrane skeleton, because of its location, serves as a scaffold, linking elements of the plasma membrane with contractile elements of the cytoskeleton and cytosolic signaling proteins, and thereby regulates such diverse functions as receptor mobility,[50,51] receptor clustering,[52-54] and signal transduction.[55] Finally, the platelet is filled with an extensive cytoplasmic network of actin filaments[47,56] organized by the actin-binding proteins filamin[57,58] and α-actinin[59] that constitute its cytoskeleton.

When platelets become exposed to components of the extracellular matrix[60] or to soluble agonists like ADP[61] or thrombin,[62,63] they undergo dramatic changes in their morphology.[64,65] The marginal band of microtubules disappears,[56] allowing the platelet to transform from a disc to an irregular sphere. At nearly the same time, the actin filament capping protein, α-adducin, becomes phosphorylated and dissociates from existing F-actin filaments,[66] exposing the barbed end of the filament to cytosolic actin monomers and driving rapid polymerization of actin into microfilaments.[64] This has the dual effect of driving the extension of lamellipodia and filopodia, and of forcing granules towards the center of the platelet where they can fuse with membranes of the OCS and release their contents to the exterior of the cell. Phosphorylation of myosin additionally induces contractile events that facilitate centralization of the granules.[67]

PLATELET GENOMICS AND PROTEOMICS

Though anucleate, platelets contain measurable and manipulable levels of megakaryocyte-derived mRNA,[25] at least some of which is capable of being synthesized into small but detectable amounts of protein.[68,69] Both serial analysis of gene expression (SAGE) and gene microarray analyses[70-72] were employed early on to estimate the size and composition of the platelet transcriptome. Of the 20,563 genes present in the human genome, 9538 distinct transcripts (6493 in the mouse) were identified in unstimulated platelets using RNA sequencing (RNA-SEQ).[73] That is considerably fewer than normally found in a nucleated cell, but perhaps more than might have been expected from an anucleate circulating cellular fragment. One of the more surprising findings in recent years has been the identification of heavy (sometimes called *heterogeneous*) nuclear RNA (hnRNA) in the platelet cytosol, as well as all of the spliceosome components necessary to splice the hnRNA into mature message that can be thereafter translated into protein.[74] Enlisted during the activation process, signal-dependent protein translation has thus far been demonstrated for mRNAs encoding interleukin (IL) 1β,[74] tissue factor,[75] and Bcl-3,[76] the protein products of which have the potential to influence inflammation, thrombosis, and wound repair. Platelets also contain an abundance of microRNAs (miRs) that have the potential, especially in precursor megakaryocytes, to regulate transcription and translation.[77]

The platelet proteome appears to be equally complex and diverse, and unlike the transcriptome, reports both the breadth as well as the relative amounts of protein products actually present in the cell. Obtained by refined two-dimensional gel electrophoretic techniques that were originally developed in the 1970s[78,79] or by liquid chromatographic separation, proteins are fragmented and separated using a combination of proteolytic and ionization techniques and then analyzed by mass spectrometry, allowing for the identification of thousands of proteins present in complex cellular lysates or subcellular fractions. In by far the most complete and quantitative profiling analyses to date, Burkhart and colleagues have identified a core platelet proteome comprised of approximately 5000 distinct platelet proteins,[80] including an abundance of molecules involved in adhesion, signaling, cytoskeletal change, and metabolism. Others have combined prefractionation methods with suitable separation techniques to describe the inventory of platelet proteins that become phosphorylated during platelet activation,[81-85] can be palmitoylated,[86] or are enriched within various subcellular compartments such as the platelet cytoskeleton,[87] platelet α-granules,[82,88-90] the membrane fraction,[91-93] membrane rafts,[94] and microparticles.[95]

ANTITHROMBOTIC COMPONENTS OF THE VESSEL WALL

Though hundreds of thousands of platelets per microliter circulate in blood, very few, if any, interact with the intact vessel wall, because the endothelial lining of the blood vessel presents an excellent nonthrombogenic surface. In fact, this property of the vessel wall has not yet been duplicated in any prosthetic or extracorporeal device. The healthy endothelium not only provides an effective barrier between blood and the highly thrombogenic components of the subendothelium (see below), but also actively produces both membrane-bound and secretory products that limit fibrin generation and promote clot dissolution. For example, heparinlike glycosaminoglycans present on the luminal side of the endothelial cell surface recruit plasma antithrombin, effecting a conformational change that promotes binding and neutralization of thrombin and other serine proteases.[96] Thrombin, when bound to the endothelial cell surface receptor, thrombomodulin, takes on anticoagulant properties via its cleavage and activation of protein C, which in turn cleaves coagulation factors V and VIII, suppressing further thrombin generation.[97] Endothelial cells also express a specific receptor for activated protein C, which serves to concentrate the protein on the endothelial surface.[98] Finally, endothelial cells synthesize, secrete and rebind tissue plasminogen activator,[99,100] which activates plasminogen to facilitate fibrin dissolution (Fig. 26-2).

The endothelial cell also produces two important inhibitors of platelet activation: prostacyclin (PGI_2)[101-103] and nitric oxide (NO). The latter was first recognized for its role as an endothelium-derived relaxation factor.[104-106] A labile oxygenated metabolite of arachidonic acid generated by endothelial cell cyclooxygenase-2 (COX-2), PGI_2 diffuses out of the cell and binds to a platelet G_s-protein coupled receptor (GPCR) known as the isoprostenoid (IP) receptor.[107,108] Its release stimulates adenylate cyclase to increase cytosolic cyclic adenosine monophosphate (cAMP) levels, which 1) activates a pump in the DTS that decreases cytosolic calcium ions (Ca^{2+}), thus helping keep platelets quiescent, and 2) activates protein kinase A (PKA). PGI_2 also has potent vasodilatory effects, binding to IP on arterial smooth muscles cells to effect vessel relaxation.[101] PGI_2 produced by the vascular endothelium thus serves to counterbalance the proaggregatory and vasoconstrictor activities of the platelet-derived prostanoid, TXA_2, the biology of which is discussed below. In fact, upsetting the delicate balance between COX-1–derived TXA_2 and COX-2–derived PGI_2 has been shown to increase the risk of adverse cardiovascular events.[109]

Whereas PGI_2 stimulates adenylate cyclase to produce cAMP, NO, a product of L-arginine generated by endothelial nitric oxide synthase (eNOS),[110] directly activates platelet guanylate cyclase, resulting in increased levels of cytosolic cyclic guanosine monophosphate (cGMP). Although platelet responses to low levels of this cyclic nucleotide can at first be mildly stimulatory,[111] cGMP, largely via its activation of protein kinase G (PKG), has the overall effect of dampening platelet responses and inhibiting platelet adhesion,[112,113] platelet aggregation,[114-117] and platelet-mediated recruitment of leukocytes during the inflammatory response (see Fig. 26-2).[118] In addition to these two soluble metabolites, endothelial cells also express on their surface a potent ADPase known at CD39, which scavenges plasma ADP to prevent platelet aggregation.[119,120] Finally, it is important to note that inflammatory cytokines, oxidized lipids, and immune complexes can, under pathologic conditions, inhibit these protective biochemical pathways and impair the antithrombotic state of the endothelial cell. These changes permit untoward formation of platelet- and fibrin-containing thrombi, as well as thrombus formation beyond sites of vascular injury, and can thus contribute to atherothrombosis.

REACTING TO THE BREACH: CELL SURFACE RECEPTORS THAT MEDIATE TETHERING AND ADHESION AND TRANSMIT EARLY ACTIVATION SIGNALS

As antithrombotic as is the endothelial lining, the underlying extracellular matrix consists of a rich mixture of glycosaminoglycans into which are embedded an abundance of highly-concentrated prothrombotic proteins, including structural components like collagen and elastin (which comprise ≈30% of body weight) and adhesive proteins such as laminin, fibronectin, and VWF. Not surprisingly, platelets have evolved receptors for most of these proteins, and a series of rapid biochemical events is initiated both on the surface and inside the cell when exposed to them. Adhesion is an activating event.

The large number of circulating red blood cells serves to marginate platelets, and when the vessel wall is breached, either by mechanical injury or after atherosclerotic plaque rupture, the first layer of platelets to encounter exposed matrix undergoes a series of sequential events similar to that which leukocytes experience during the

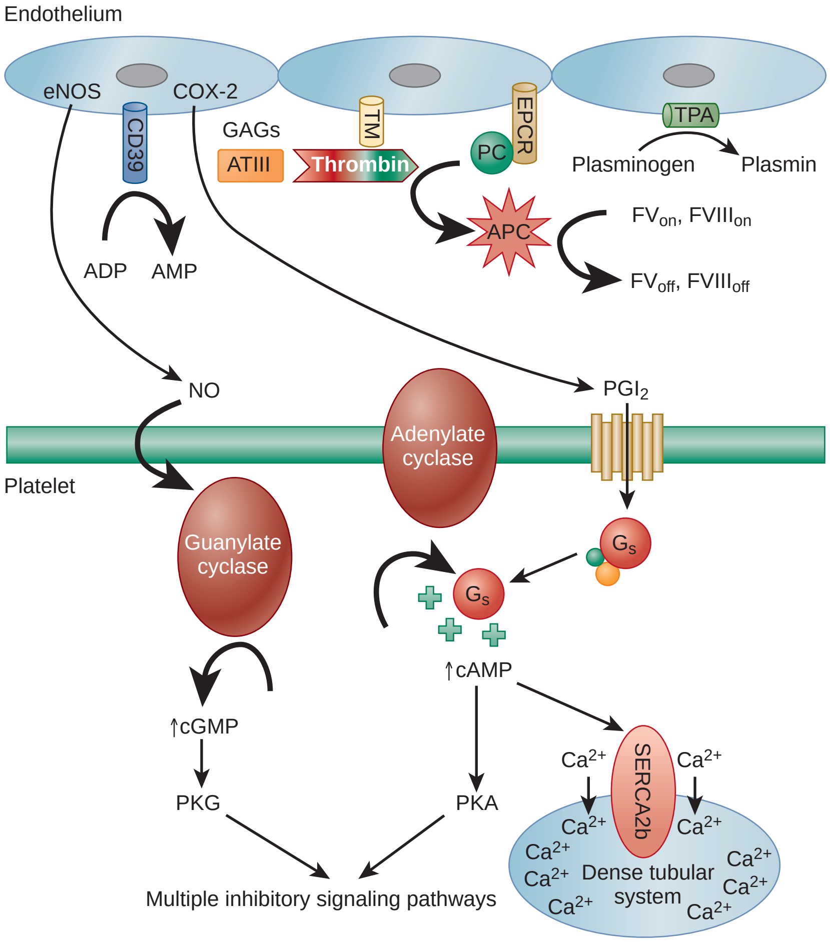

Figure 26-2 Anticoagulant and antithrombotic components of the vascular endothelium. Endothelial cells produce a number of substances, including NO and PGI$_2$ that act on platelet surface receptors to dampen platelet responsiveness. They also scavenge the platelet agonist ADP, inactivate thrombin, and activate the fibrinolytic enzyme plasmin. *ADP,* Adenosine diphosphate; *AMP,* adenosine monophosphate; *APC,* activated protein C; *Ca^{2+},* calcium ion; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *COX-2,* cyclooxygenase-2; *GAGs,* glycosaminoglycans; *eNOS,* endothelial nitric oxide synthase; *EPCR,* endothelial cell protein C receptor; *NO,* nitric oxide; *PC,* protein C; *PGI$_2$,* prostacyclin; *PKA,* protein kinase A; *PKG,* protein kinase G; *SERCA2b,* sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase; *TM,* thrombomodulin; *TPA,* tissue plasminogen activator.

inflammatory response—namely tethering, initial signaling to the cell interior, integrin-mediated adhesion, and cytoskeletally-directed cell spreading. Whereas leukocyte tethering is mediated by members of the selectin family, the first layer of platelets become tethered on VWF,[121] which is sprinkled on exposed collagen fibers via interactions with a high-affinity, platelet-specific, multi-subunit receptor known as the *GPIb/V/IX complex*.[122] This complex, which is expressed at approximately 25,000 copies/platelet,[123] binds to the A1 domain of VWF[124] with sufficiently high affinity to tether platelets even under conditions of arterial shear.[125] Loss of this receptor in both humans and mice results in a clinical condition known as *Bernard-Soulier syndrome,*[14,15] which is characterized not only by an increase in platelet size but also by prolonged bleeding caused, in large part, by the inability of platelets to adhere to the vessel wall. After engagement with its ligand, GPIb acts through membrane-proximal Src family kinases,[126] adapter molecules,[127] and to a lesser extent via its association with immunoreceptor tyrosine-based activation motif (ITAM)–bearing subunits[128,129] to transmit early activation signals.[130,131] Together the result is the recruitment and activation via tyrosine phosphorylation of phospholipase Cγ2 (PLCγ2),[132,133] a key enzymatic component of platelet amplification that is required to achieve thrombus growth and stability (Figure 26-3).[134]

Once tethered, two different platelet integrins—each of which exists in a low-affinity state on the platelet surface—begin to engage specific extracellular matrix components, and together with the small calcium transients and kinase-generated signals emanating from the GPIb complex, and from mechanical shear forces generated by the flowing blood,[135] initiate the reciprocal processes of platelet adhesion and activation. Thus the integrin $\alpha_2\beta_1$ binds to exposed collagen fibrils,[136] and the integrin receptor $\alpha_6\beta_1$ engages laminin.[137] Both of these integrins "hand off" to a member of the immunoglobulin superfamily, glycoprotein VI (GPVI),[138,139] which via its non–covalent association in the plane of the plasma membrane with the ITAM-bearing Fc-receptor γ-chain homodimer,[138,140] elicits strong PLCγ2-dependent events that 1) begin the process of cytoskeletally-directed shape change and cell spreading; 2) initiate signal transduction pathways that cause dramatic structural changes

Figure 26-3 Platelet adhesion receptors that signal through PLCγ2. Each of the cell surface receptors shown recognizes different components of the extracellular matrix, and thus they work in coordinated fashion to send early activation signals into the cell. Binding of platelets to VWF slows platelets down so that integrins associate productively with matrix collagen and laminin. Signals emanating from each of these events are transmitted into the cell interior, in part via the action of receptor-associated Src family kinases (Src, Fyn, Lyn), which phosphorylate tyrosine residues within nearby ITAMs, thus forming a nucleation point for the assembly of miniature organelles sometime referred to as *signalosomes*. Signalosomes are themselves comprised of the adaptor proteins LAT, SLP-76 and Gads and the receptor tyrosine kinase BTK, and they function to localize, phosphorylate, and then activate PLCγ2, which coordinates all these responses by generating the classical signaling molecules IP3 and DAG. Details regarding the molecular events that take place after generation of IP3 and DAG are found in Figures 26-4 and 26-6. *CRP,* C-reactive protein; *DAG,* diacylglycerol; *DTS,* dense tubular system; *GP,* glycoprotein; *IP$_3$,* 1,4,5-inositol triphosphate; *ITAM,* immunoreceptor tyrosine-based activation motif; *PKC,* protein kinase C; *PLCγ2,* phospholipase Cγ2; *VWF,* von Willebrand factor.

in platelet integrins (see Fig. 26-3), resulting in their adopting a high-affinity, ligand-binding–competent conformation[141] (a process known as “inside-out” signal transduction); and 3) facilitate fusion of α- and δ-granules with the OCS and underlying plasma membrane. Other cell-surface receptors that participate in adhesion-initiated activation events include PEAR1,[142] FcγRIIa,[143] and the C-type lectin receptor, CLEC-2.[144]

PLATELET GRANULES AND THEIR ROLE IN HEMOSTASIS

Platelet-specific granules are synthesized, assembled, and packaged during megakaryocyte biogenesis, and at later stages of maturation they appear to come into contact with microtubules. The microtubules then transport them, via the microtubule motor protein kinesin, along the shafts of proplatelets until they reach the proplatelet tips.[145] Once inside a mature platelet, platelet granules remain relatively evenly dispersed throughout the cytoplasm, their contents awaiting threshold signals for cellular activation, at which time their membranes fuse with those of the plasma membrane, or more likely, the invaginated subdomains of the OCS.[146] The regulated secretion of granule contents ensures that hemostasis remains highly localized, an event that has been exploited to deliver non–platelet-derived procoagulant proteins like Factor VIII to sites of vascular injury.[147,148]

Box 26-1 **Platelet Granules and Their Contents**

A. α-Granules
  1. Membrane proteins enriched in the granule membrane: P-selectin, TLT-1, CD40 ligand (which is cleaved after exposure on the platelet surface to release soluble CD40L), and tissue factor.
  2. Membrane proteins present at similar concentrations as they are in the plasma membrane: GPIIb-IIIa, GPIb, PECAM-1, and perhaps many others
  3. Granule contents:
    a. Synthesized by megakaryocytes: thrombospondin, VWF, PF4, β-thromboglobulin, PDGF
    b. Endocytosed from plasma or origin not determined: albumin, fibrinogen, fibronectin, IgG, Gas6, coagulation factor V, and many chemokines and growth factors, including RANTES, bFGF, EGF, TGFβ, and VEGF
B. Dense (δ) granules: ADP, ATP, 5′-HT, Ca^{++}, polyphosphate
C. Lysosomes: acid hydrolases, elastase, cathepsins, and other degradative enzymes

5′-HT, 5′-hydroxytryptamine; *ADP,* adenosine diphosphate; *ATP,* adenosine triphosphate; *Ca^{2+},* calcium ion; *EGF,* epidermal growth factor; *FGF,* fibroblast growth factor; *IgG,* immunoglobulin G; *PDGF,* platelet-derived growth factor; *PF4,* platelet factor 4; *RANTES,* regulated on activation, normal T-cell expressed and secreted; *TGF,* transforming growth factor; *VFW,* von Willebrand factor.

Platelets harbor three distinct types of granules (Box 26-1). Two, α-granules and dense (δ) granules, are found only in platelets, whereas lysosomes are present in nearly all cell types. α-Granules are by far the most numerous, with as many as 40 to 80 per cell, and they contain a wide array of proteins and bioactive peptides. Box 26-1 classifies α-granule proteins as those that reside within the α-granule membrane (P-selectin being the most diagnostic), those pinocytosed from plasma and packaged (IgG, fibrinogen, albumin),[149] and those synthesized by megakaryocytes and stored (VWF, platelet factor 4, thrombospondin). mRNAs encoding the latter group have all been identified in the platelet cytoplasm. Upon platelet activation, granules redistribute toward the center of the cell,[146] at which time soluble *N*-ethylmaleimide–sensitive attachment protein receptor (SNARE) proteins within the α-granule membrane facilitate fusion[150,151] with members of the Rab family of low–molecular-weight GTPases playing a prominent role in vesicle docking and exocytosis.[152,153] After membrane fusion, P-selectin[154-156] and α-granule membrane-specific proteins like TLT-1[157] become expressed on the platelet surface, and the contents of the granule are released into the plasma milieu. Exposed P-selectin, diagnostic of an activated platelet,[158,159] serves to recruit leukocytes to the site of injury,[160] constituting one of a number of important links between thrombosis and inflammation.[161] Proteins secreted from the platelet include the adhesive ligands VWF and fibrinogen, which serve to support platelet–platelet interactions, growth factors and cytokines that promote cell migration,[162] wound healing,[163] maintenance of vascular integrity,[164] and autocrine factors like growth-arrest–specific gene 6 (Gas6)[165] and CD40L[166] that are released and rebind platelet receptors to help amplify platelet responsiveness. Finally, α-granules and their contents are a source of procoagulant proteins, releasing Factor V[167] and exposing tissue factor[75,168] to promote localized fibrin deposition at sites of vascular injury. Platelet α-granules, or at least their contents,[169] are severely reduced in an inherited bleeding disorder known as the *gray platelet syndrome (GPS)* (see Chapter 30).[170-173]

Dense granules (four to eight per platelet) are morphologically distinct, electron-opaque storage organelles that contain the vasoconstrictive substance serotonin,[174,175] adenine and guanine nucleotides like ADP and ATP, inorganic pyrophosphates[176] and polyphosphates,[177,178] and Ca^{2+}.[179] Complexes of the latter two are likely responsible for the dark appearance of these bodies in thin section electron microscopy.[180] Dense granule membranes contain a few components in common with lysosomal membranes, like granulophysin (CD63, lysosomal associated membrane protein [LAMP]-3)[181] and LAMP2,[182] as well as membrane proteins also present in α-granule membranes, like P-selectin,[181] suggesting a common origin during biogenesis. Like α-granule membrane proteins, these become expressed on the platelet-cell surface after granule fusion and secretion and can be used as platelet activation markers. Curiously, a number of plasma membrane GPs, including GPIb and GPIIb-IIIa, have also been reported in dense granule membrane.[183] Dense granule contents, especially ADP,[184] play a physiologically important role in hemostasis, as evidenced by characteristic platelet function defects in patients whose platelets lack dense granules or their contents,[185] collectively known as *storage pool disorders*.[186-188] Chédiak-Higashi and Hermansky-Pudlak[189] syndromes are two such examples of autosomal recessive dense granule defects that lead to platelet dysfunction and bleeding, the former being associated with immunodeficiency and the latter with albinism (see Chapter 30).

Primary lysosomes are the third organelle whose contents are secreted upon platelet activation, though only three or fewer per cell are normally identifiable.[190] Though a clear role for lysosomes in platelet function has not been identified, they do contain more than a dozen different acid hydrolases, cathepsins D and E, and other degradative enzymes that can be secreted if platelets are subjected to strong agonist stimulation. Their contents have been shown to be mildly reduced in the platelets of individuals with GPS,[191] in keeping with the notion that GPS is caused by a defect in packaging.[171-173] Membrane proteins on platelet lysosomes are typical of lysosomes in other cells, and include LAMP-1,[192] LAMP-2,[182] and LAMP-3.[181]

FEED-FORWARD AMPLIFICATION PATHWAYS INVOLVED IN PLATELET RECRUITMENT AND THROMBUS STABILITY

Although platelet adhesion, early activation signals, and granule release are necessary prerequisites for thrombus formation, efficient recruitment of additional platelets to the site of the vascular lesion to yield a stable platelet plug requires a host of additional receptor/ligand interactions, each of which results in signal transmission and therefore biochemical and cell biological changes that help sustain platelet activation. Among the most important of these is the binding of released ADP to one of its two platelet G-protein–coupled receptors, P2Y_{12}.[193,194] Like the α_2 receptor for epinephrine, P2Y_{12} is coupled to an inhibitory G protein that slows down the activity of adenylate cyclase, thus lowering cytosolic levels of cAMP (Fig. 26-4). This greatly potentiates platelet responses to other agonists, because it allows calcium ions (released from the DTS as a result of the action of phospholipase-generated 1,4,5-inositol trisphosphate [IP_3]) to remain cytosolic. "Bioavailable" calcium ions in turn support a host of additional cellular events, including more robust granule secretion, activation of metal ion-dependent proteases, and activation of cell surface integrins. The importance of ADP in amplifying platelet responses is illustrated by the clinical effectiveness of ticlopidine and clopidogrel—widely-used pharmacological agents that antagonize the activity of P2Y_{12}—in pacifying platelet reactivity and inhibiting platelet aggregation.[195]

In addition to ADP-induced, P2Y_{12}-mediated signaling, there are nearly a dozen other soluble ligands that are either generated or released at sites of vascular injury and that function in signal amplification and platelet activation. These can be broken into three classes according to the type of platelet receptor to which they bind (Fig. 26-5). The first class of ligands is comprised of ADP, thrombin, TXA_2, and serotonin (5′-hydroxytryptamine), each of which bind to a specific GPCR that is coupled to

Figure 26-5 Agonist receptors that initiate and/or amplify platelet activation responses. Three different families of receptors are involved in signal amplification pathways: Gq-coupled GPCRs, integrins, and RTKs. Note how each activates either the γ or β isoform of PLC. The sum total of PLC-generated products serves to determine the activation state of the platelet, its ability to respond to vascular injury, and its participation in thrombus growth. *5′HT,* 5′-Hydroxytryptamine; *ADP,* adenosine diphosphate; *DAG,* diacylglycerol; *DTS,* dense tubular system; *GPCR,* G_s-protein coupled receptor; *IP_3,* 1,4,5-inositol triphosphate; *ITAM,* immunoreceptor tyrosine-based activation motif; *PLC,* phospholipase C; *RIAM,* $Rap1_{GTP}$-interacting adaptor molecule; *RTK,* receptor tyrosine kinase; *VWF,* von Willebrand factor.

the heterotrimeric a subunit, Gq. Thus ADP binds to P2Y$_1$,[196-200] thrombin to the protease activated receptors PAR1 and PAR4,[201,202] TXA$_2$ to the thromboxane receptor,[203,204] and serotonin to 5HT2A.[205] When released as a consequence of ligand binding to any of these GPCRs, the Gq subunit binds to the β isoform of phospholipase C (PLC). PLCs are lipid hydrolases that act on membrane-associated phosphatidylinositol (PI)–4,5-P$_2$ to produce the second messengers IP$_3$ and diacylglycerol (DAG). IP$_3$ binds and opens calcium channels, and DAG activates the most abundant forms of protein kinase C (PKC), initiating additional signaling cascades downstream of this serine/threonine kinase. As shown in Figure 26-5, it is the sum of these products—generated by the γ2 isoform of PLC in response to adhesion and by the β isoform of PLC in response to ligand-GPCR interactions—that the platelet integrates when deciding whether to become fully activated. This concept is important in the context of designing pharmacologic strategies to inhibit platelet function, because blocking adhesion and its consequent activation of PLCγ2 leaves PLC β-mediated platelet activation largely intact and vice versa.

The second class of signal amplifiers is the cell surface integrins themselves.[206] As illustrated in the middle section of Figure 26-5, when ligands bind to integrins, Src-family kinases (SFKs) associated with integrin cytoplasmic tails[207] trigger a series of incompletely understood SFK-mediated amplification events[208] that have been collectively termed *outside-in signaling*.[209-211] This has recently been demonstrated after interaction of the major platelet integrin αIbβ$_3$ with its ligand fibrinogen;[212] however, signals also emanate from α$_2$β$_1$[141,213,214] and α$_6$β$_1$[139] when platelets encounter collagen and laminin at sites of vascular injury. Activation signals from the latter two may be relatively weak by comparison, owing to the fact that only a few thousand of each are expressed on each platelet, compared with 50 to 80 thousand αIbβ$_3$ receptors per cell.[215,216] Protein kinases Syk and FAK have been shown to become activated downstream of αIIbβ$_3$ engagement, as has PLCγ$_2$.[217] However, the details of these events remain to be worked out. A less well-defined autocrine loop that utilizes integrin-mediated outside-in signal amplification is the cleavage and rebinding of soluble CD40L after α-granule fusion and secretion.[166]

The third class of feed-forward amplification reactions is mediated by ligand-activated plasma membrane receptor tyrosine kinases (RTKs). The first of these to be described were receptors for Gas6, a vitamin K-dependent protein related to the anticoagulant protein S. Gas6 is thought to reside in platelet α-granules,[218,219] and like other α-granule proteins, becomes secreted upon platelet activation. Interestingly, platelets have three different receptors for Gas6: Axl, Sky, and Mer, all of which have active cytoplasmic tyrosine kinase activity (see Fig. 26-5). Upon engagement, Gas6 receptors trigger tyrosine phosphorylation of the β$_3$ integrin cytoplasmic domain and thereby support outside-in integrin signaling, as well as activate PI3-kinase to further sustain granule secretion.[220] Platelets also express two members of the Eph receptor tyrosine kinase family, EphA4 and EphB1, which when in contact with their membrane-bound counter-receptor, Ephrin B1, stimulate tyrosine phosphorylation of the integrin β$_3$ tail and activate the integrin activator, Rap1b.[221] Like Gas6 signaling,[165,222,223] genetic loss or pharmacologic blockade of Ephrin/Eph kinase interactions results in decreased ability to form a stable thrombus or retract a fibrin clot.[224]

ACTIVATION OF THE MAJOR PLATELET INTEGRIN, αIIBβ$_3$ (GPIIB-IIIA COMPLEX): THE FINAL COMMON ENDPOINT OF PLATELET ACTIVATION.

Human platelets express at least five different members of the 24-member integrin family,[211,225] including three β1 integrins (α$_2$β$_1$, α$_5$β$_1$, and α$_6$β$_1$—specific for collagen, fibronectin, and laminin, respectively) and two β$_3$ integrins—avβ$_3$ and its close relative, αIIbβ$_3$ (also known as the GPIIb-IIIa complex). αIIbβ$_3$ is by far the most abundant and well-studied. This section will focus on our current understanding of how αIIbβ$_3$ becomes transformed from a resting to an active, ligand binding-competent conformation, with the understanding that the biochemical and cell biological principles described for this integrin may well apply to the others.

As shown in schematic form on the left side of Figure 26-6, αIIbβ$_3$ exists on the platelet surface in a bent-over conformation that is unable to associate effectively with its major soluble ligands, fibrinogen, VWF, and fibronectin.[226,227] Though relatively short, the cytoplasmic domains of αIIb and β$_3$ are thought to play a key role in maintaining the “off” state of this integrin complex, owing to weak charge interactions between them[228,229] that allow the hydrophobic transmembrane domain helices of each subunit to interact and maintain the integrin in a low-affinity state.[230,231] When platelets become activated—either by adhesion– or soluble-agonist–mediated events—calcium and DAG, generated as a result of the actions of PLCγ2 and PLCβ (see Figs. 26-3 and 26-5), bind to and activate PKC and the guanine exchange factor, CalDAG-GEF1. As illustrated in Figure 26-6, each of these can independently activate Rap1,[232-236] a low molecular weight GTPase that has been implicated in integrin activation.[237-239] Rap1 activates integrins via an effector molecule known as the *Rap1$_{GTP}$-interacting adaptor molecule (RIAM),* which recruits the highly abundant cytosolic protein, talin to the inner face of the plasma membrane, forming an integrin activation complex. Binding of RIAM-associated talin to the β$_3$ integrin subunit represents the final common step in integrin activation,[240,241,242] because it disrupts the weak ionic clasp between the αIIbβ$_3$ tails, allowing for tail separation[243] and a dramatic, rapid unfolding of the extracellular domain.[227] Simultaneous conformational changes in the integrin head[244,245] result in formation of an integrin receptor having high affinity for its soluble adhesive ligands. In a still-to-be-defined mechanism, the cytoskeletal protein kindlin 3 then contributes to activating and/or maintaining the activation state of αIIbβ$_3$.[246,247] As integrin-rich adhesion complexes mature, the cytoskeletal protein vinculin takes over for the nascent Rap1/RIAM complex and stabilizes adhesions.[248] Finally, integrins

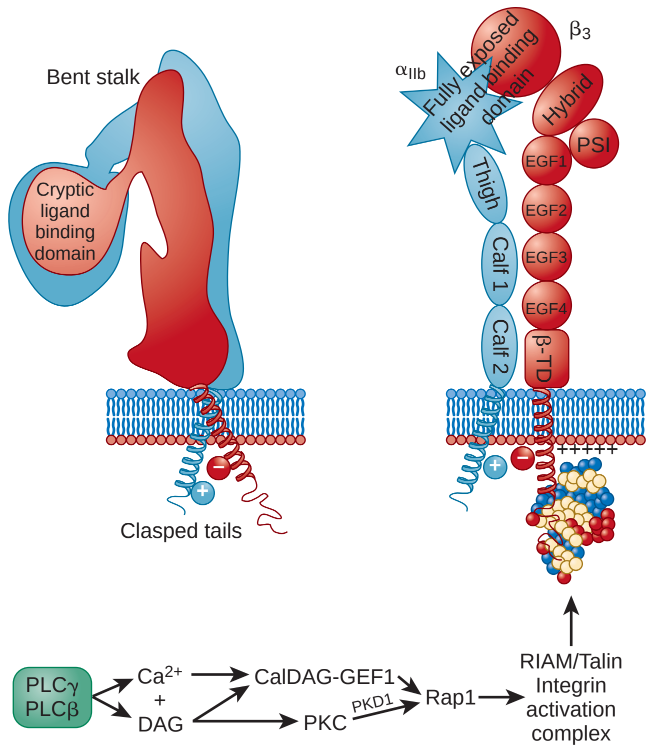

Figure 26-6 Integrin activation. Calcium and DAG, generated as a result of the combined actions of PLCγ and PLCβ, activate two proteins: PKC and the Rap guanine exchange factor, CalDAG-GEF1. Each of these is able to independently activate the small GTPase, Rap1. In its GTP-bound form, Rap1 binds to and activates one of its effector molecules, RIAM, which then binds talin, forming an integrin activation complex (IAC). When the IAC binds specific sites within the β_3 cytoplasmic domain, the clasp breaks, thereby destabilizing transmembrane domain helix associations that are thought to maintain the integrin in its low-affinity state. Breaking the hinge causes extensive conformational changes in the extracellular domain to produce a high-affinity, ligand binding-competent integrin. *DAG,* Diacylglycerol; *PKC,* protein kinase C; *PLC,* phospholipase C; *RIAM,* Rap1GTP-interacting adaptor molecule. *(Modified from Wegener, Partridge AW, Han J, et al: Structural basis of integrin activation by talin.* Cell *128:171, 2007.)*

cluster,[249] ensuring that bound ligands effectively broker with high avidity the platelet–platelet interactions that permit thrombus growth and stabilization.

CELL SURFACE AND CYTOSOLIC PROTEINS THAT LIMIT PLATELET RESPONSIVENESS

As anyone who has witnessed a myocardial infarction or thrombotic stroke will know, unrestrained thrombus growth at inappropriate sites can be as harmful as excessive bleeding, because it can result in vessel occlusion, ischemia, and tissue damage. Numerous active processes are in place to limit platelet responsiveness in healthy vessels, to keep thrombus growth localized to specific sites of vascular injury, and to facilitate dissolution of a platelet plug during recovery.

Exogenous inhibitors of platelet function produced by a healthy endothelial lining contribute to platelet passivation via continuous generation of PGI_2 and NO, which act on platelets by activating adenylate and guanylate cyclases to increase intracellular levels of cAMP and cGMP, subsequently activating PKA and PKG (see Fig. 26-2). PKG controls the threshold for platelet activation primarily by phosphorylating the IP_3 receptor-associated cGMP (IRAG) kinase substrate,[250] a protein that associates with PKG and IP_3 receptor type I to inhibit IP_3-induced calcium release from intracellular stores.[251,252] Both PKA and PKG interfere with platelet activation by phosphorylating and inactivating vasodilator-stimulated phosphoprotein (VASP),[253] a molecule with anticapping activity that is important for the processes of actin polymerization and filopod formation.[254-258] PKCδ also binds VASP and interferes with its ability to promote filopodia formation, although this pathway is unique to collagen-stimulated platelets and does not involve regulation of PKA- or PKG-mediated VASP phosphorylation.[259]

In addition to exogenous inhibitors, platelets themselves contain a plethora of inhibitory proteins designed to keep platelet activation in check, either by setting a threshold for platelet activation or by turning off activation signals once sufficient platelet responses have occurred. Regulator of G-protein signaling (RGS) proteins modulate GPCR-mediated platelet accumulation and thrombus formation at sites of vascular injury,[260,261] as do members of the β-arrestin family.[262] Platelets also express three members of the immunoglobulin gene–immunoreceptor tyrosine-based inhibitory motif (Ig-ITIM) family of inhibitory receptors, PECAM-1,[263-266] CEACAM-1,[267] and G6b-B,[92,268,269] each of which contains in its cytoplasmic domain tyrosine residues that, when phosphorylated form docking sites for phosphatases that function to shut down tyrosine kinase–dependent signaling reactions.[270-272] Interestingly, one of the five tyrosine kinases present in platelets, Lyn, actually limits platelet aggregation both in response to GPVI-specific stimuli[273] and after platelet spreading on immobilized fibrinogen,[274] perhaps via its ability to phosphorylate the ITIM tyrosines of PECAM-1.[275,276]

Several inhibitory pathways have been identified in platelets that either regulate, or are regulated by PI3 kinase, a lipid kinase that phosphorylates the 3′ position of PI 4,5-diphosphate (PIP_2) to generate PI 3,4,5-triphoshate (PIP_3), thereby creating docking sites on the inner face of the plasma membrane for pleckstrin homology (PH) domain–containing molecules.[277] The actions of PI3-kinase are opposed by the lipid phosphatase, SH2 domain-containing inositol 5′-phosphatase 1 (SHIP1), which hydrolyzes the 5′-phosphate of PIP_3.[278,279] In platelets, SHIP1 has been shown to downregulate PIP_3 generation after $\alpha IIb\beta_3$-mediated outside-in signaling,[274] and thus it may interfere with feed-forward amplification pathways that increase the efficiency with which platelets are recruited to growing thrombi. Interestingly, the 5′-inositol phosphatase activity of SHIP1 appears to be enhanced at least in part by the actions of the Src-family tyrosine kinase,

Akt (also known as *protein kinase B*) is a PH domain–containing serine/threonine kinase that is a well-characterized effector of PI3 kinase.[280,281] Akt contributes positively to platelet activation in multiple ways, one of which appears to be by inactivating the serine/threonine kinase, glycogen synthase kinase 3 (GSK3). The GSK3 family is comprised of three isoforms (α, β, β_2) that are constitutively active in resting cells but which become inactivated in activated cells by Akt-mediated phosphorylation.[282] Platelets express two isoforms of GSK3 (α and β), both of which become phosphorylated and inactivated after exposure of the platelet to multiple agonists that activate PI3 kinase and Akt.[283] Whereas initial studies reported that specific inhibitors of GSK3 activity block rather than enhance platelet responses to agonist stimulation,[283] more recent data implicate the β isoform of GSK3 as a negative regulator of platelet function both in vitro and in vivo.[284] Finally, the serine/threonine kinase PKCδ has also been shown to negatively regulate platelet activation after platelet exposure to collagen.[259,285]

NONHEMOSTATIC ROLES FOR PLATELETS: BLOOD VESSEL MAINTENANCE AND REPAIR, INFLAMMATION AND INFECTION, AND ATHEROTHROMBOSIS

In addition to being essential for primary hemostasis, activated platelets and their secreted products have the ability to influence a broad array of pathophysiologic processes. These include leukocyte trafficking and inflammation, tissue regeneration and angiogenesis, and both the beginning and end stages of atherosclerosis.

Activated platelets that become spread on components of the extracellular matrix or on each other display an altered surface phenotype, the most prominent of which is exposure of several thousand copies of the α-granule-derived membrane protein, P-selectin. P-selectin is also expressed on cytokine-activated endothelial cells. Thus after either a thrombotic or inflammatory event, P-selectin appears on the luminal face of the vessel wall, where it serves to recruit monocytes and neutrophils into the underlying tissue by binding PSGL-1, a constitutively expressed counter-receptor for P-selectin that is present on most leukocytes. In vivo, mice lacking P-selectin exhibit greatly diminished leukocyte rolling, delayed recruitment into sites of inflammation, and increased susceptibility to infection.[286,287] Whereas endothelial P-selectin no doubt has a major role in leukocyte capture, platelet P-selectin likely plays a prominent role in "secondary capture."[288,289] As in platelets, tethering also initiates activation of leukocyte integrins, which are then able to mediate cell spreading and transendothelial migration. P-selectin–PSGL-1 interactions therefore constitute an important link between thrombosis and inflammation.[161,290] Other platelet/leukocyte receptor–counter-receptor pairs have also been shown to facilitate the inflammatory response, including binding of platelet-associated fibrinogen binding to the leukocyte integrin, MAC-1[291] and platelet JAM-3 binding to MAC-1 on monocytes[292] and dendritic cells.[293]

In addition to forming a platform for leukocyte recruitment during acute inflammation, platelets also deliver to the vessel wall proinflammatory chemokines that are thought to play roles in the development of atherosclerosis by promoting further chemoattraction of leukocytes and by stimulating proliferation of vessel wall smooth muscle cells and fibroblasts. Such secreted factors include the C-X-C chemokine platelet factor 4, macrophage inflammatory protein (MIP) 1a, the C-C chemokine regulated on activation, normal T-cell expressed and secreted (RANTES), CD40 ligand, platelet-derived growth factor (PDGF), and TGFβ.[161,290,294,295] Activated platelets also synthesize *de novo* IL 1β,[74,296,297] a potent stimulator of endothelial cells and monocytes that upregulates adhesion molecule expression. Thus platelets appear to contribute in a number of ways to the development and progression of atherosclerotic lesions.

So as not to leave the reader with the impression that platelets only exacerbate chronic human disease, it should be noted that as early as 1969[164] platelets and their secreted products were shown to be able to "nurture" the vascular endothelium. They are increasingly used as a source of biological response modifiers in a plethora of conditions, including organ preservation, gum restoration after dental procedures, and tissue repair after surgery.[163] The ability of platelets to adhere to sites of vascular injury and secrete both degradative enzymes and at the same time growth-promoting factors like vascular endothelial growth factor (VEGF), PDGF, fibroblast growth factor (FGF), epidermal growth factor (EGF) and angiopoietin 1 allows them to play a uniquely supportive role in endothelial cell migration and survival during the process of wound healing and angiogenesis.[162] Platelet-rich plasma to treat bone and cartilage repair after sports injuries, though largely unsubstantiated, is also finding increasing use.[298-301] Platelet-secreted factors have also been shown to have a critical role during the time when embryonic blood vessels and lymphatic vessels separate during development[302,303] in a mechanism that involves binding of the ITAM-bearing platelet receptor CLEC-2 to the lymphatic endothelial marker podoplanin.[304] Blood flow also appears to be a critical regulator of this developmental event.[305] Platelet secreted products also play a vital role in another developmental event, namely closing of the ductus arteriosis.[306] Finally, platelets bind via their cell-surface CD36 receptor to malarial-infected red blood cells, an event that induces secretion of platelet factor 4 (PF4) from platelet α granules. PF4 in turn binds to the Duffy antigen on the red blood cells, causing lyses of the parasite digestive vacuole, ultimately killing the parasites within.[307,308]

CONCLUSION

OVERVIEW OF COAGULATION

Generation of the enzyme thrombin from its precursor prothrombin is the central event in the blood coagulation process, essential for hemostasis and the culprit in thrombosis. Blood loss through lack of hemorrhage control has captured the attention of individuals from many walks of life throughout history. At the end of the nineteenth century, the role of thrombin in the clotting of fibrinogen was accurately described by Schmitt.[1] Since that time hemostasis has been synonymous with blood clotting. Congenital diseases associated with absence or reduced production of thrombin (the hemophilias) represent important clinical problems (see Chapters 31 and 32). In contrast, the unregulated production of thrombin in an inappropriate location leads to another series of diseases associated with thrombotic occlusion (see Chapter 33).

The development of plasma clot–based assays in vitro has played a central role in establishing the logical relationships between the reactants and reactions of hemostasis (Fig. 27-1). The prothrombin time (PT) and the activated partial thromboplastin time (APTT) both rely on the end point of fibrin formation (clotting), which occurs with the generation of less than 5% of the thrombin ultimately produced. The primary pathway leading to hemostatic and thrombotic pathology appears to be associated with the tissue factor (TF)–initiated, “extrinsic” coagulation pathway. In contrast, components unique to the “intrinsic,” or contact, pathway (factor XII, prekallikrein, high–molecular-weight kininogen [HMWK]) do not appear to be essential to hemostasis.

The observation that tissue extracts added to plasma initiated clotting led Quick to develop the PT assay.[2] This assay is still used extensively in the management of warfarin anticoagulant therapy and establishes the continuity of components in the *extrinsic pathway*. The tissue preparations (thromboplastin) contain the protein TF and

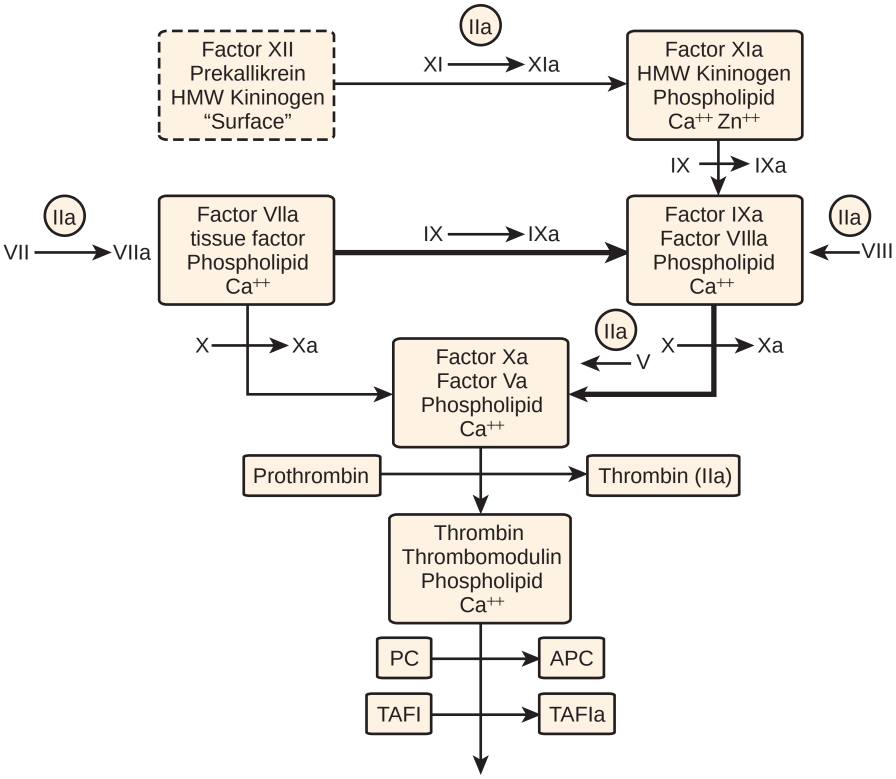

Figure 27-1 Schematic of the catalysts of the hemostatic system. The outline of the "contact catalyst" of the intrinsic pathway is dashed because of its uncertain contributions to hemostasis. The contribution of the contact catalyst to thrombosis is unresolved. The various points at which thrombin catalyzes its own generation by the conversion of zymogens and procofactors to the active species required for catalyst formation are illustrated by circles (IIa). *APC,* Activated protein C; *HMW,* high–molecular-weight; *PC,* protein C; *TAFI,* thrombin-activatable fibrinolysis inhibitor.

phospholipids, with plasma contributing factor VIIa and calcium to form the *extrinsic factor Xase*, which converts plasma factor X to factor Xa (see Fig. 27-1). Factor Xa subsequently combines with plasma factor Va, phospholipids, and calcium to activate prothrombin to thrombin, the latter serving as the catalyst that cleaves fibrinogen to produce fibrin, the clotting end point.

Langdell and colleagues[3] subsequently explored the spontaneous clotting of recalcified citrate plasma and developed the APTT, thus providing the tool that defined the *intrinsic pathway* of coagulation (see Fig. 27-1). This pathway, dependent only on the protein components present in blood plasma, was formalized by the cascade/waterfall hypotheses of MacFarlane[4] and Davie and Ratnoff.[5] The APTT assay involves the addition of an artificial surface, phospholipids, and calcium chloride to blood plasma. Initiation of this contact pathway begins with the surface-dependent activation of factor XII to factor XIIa; this leads to activation of prekallikrein to kallikrein, which, together with HMWK, provides a self-amplifying catalytic system that results in rapid activation of factor XI to factor XIa. Factor XIa, together with HMWK, phospholipid, and metal ions, catalyzes the activation of factor IX to factor IXa. Factor IXa, with factor VIIIa and a membrane surface, form the *intrinsic factor Xase*, which activates factor X to factor Xa as illustrated in Figure 27-1.

By the mid-1980s, the conclusion that TF was probably the principal initiator of the hemostatic process[6] and the absence of bleeding associated with deficiencies of the contact pathway initiators (factor XII, prekallikrein, and HMWK) presented a significant conundrum for the scientific community. This was accentuated by the absence of linkage between hemophilia A and B and the extrinsic pathway as evaluated by the PT assay. Subsequently, the intersections between intrinsic and extrinsic and the reactions linking these two "classical" pathways were identified.[7,8,9]

Of equal importance to the procoagulant process is its regulation by stoichiometric and dynamic inhibitory systems. Antithrombin (AT)[10] and tissue factor pathway inhibitor (TFPI)[11] are the primary stoichiometric inhibitors, whereas the thrombin-thrombomodulin–protein C system is dynamic in its inhibitory function. The latter catalyst activates protein C to activated protein C (APC), which proteolytically destroys the cofactors factor Va and factor VIIIa, thereby eliminating the intrinsic factor Xase and prothrombinase. TFPI blocks the factor VIIa–TF–factor Xa product complex,[12] thus effectively neutralizing the extrinsic factor Xase (Fig. 27-2). However, TFPI is present in low abundance (≈2.5 nM) in blood and can only delay the hemostatic reaction.[13] AT, normally present in plasma at twice the concentration (≈2 to 3 μM) of any potential coagulation enzyme, neutralizes all the

Figure 27-2 Points of regulation of the catalyst of Figure 27-1 by tissue factor pathway inhibitor (TFPI), antithrombin III (AT), and activated protein C (APC) are illustrated. *HMW,* High–molecular-weight; *PC,* protein C; *TAFI,* thrombin-activatable fibrinolysis inhibitor.

procoagulant serine proteases, primarily in the uncomplexed state.[10]

The dynamic protein C system is activated by binding of thrombin to vascular thrombomodulin, with this complex (Fig. 27-3) converting protein C to its activated species APC.[14] APC proteolytically inactivates factors Va and VIIIa.[15] The protein C system, TFPI, and AT cooperate to produce steep TF concentration thresholds that act like a digital "switch" to allow or block thrombin formation.

Thus there are three membrane-associated procoagulant complexes[16] (corresponding to the proteases factor IXa, factor Xa, and factor VIIa), each interacting with a cofactor protein (factor VIIIa, factor Va, TF). An analogous anticoagulant complex is composed of thrombin-thrombomodulin (see Fig. 27-3). Each complex involves a vitamin K–dependent serine protease, phospholipid, and an associated cofactor protein assembled on a membrane surface provided by an exposed, activated or damaged cell.

The membrane-binding properties of the vitamin K–dependent proteins (VKDPs) are the consequence of posttranslational γ-carboxylation of these macromolecules. The cofactor proteins are either membrane-binding proteins (factor Va, factor VIIIa) recruited from plasma as procofactors or intrinsic membrane proteins (TF, thrombomodulin) regulated by presentation. Each complex catalyst is orders of magnitude (10^3- to 10^6-fold) more efficient than the individual serine protease acting on its substrate in solution.[17-19] When considered on a temporal scale, the amount of thrombin produced

Figure 27-3 Vitamin K–dependent complexes. Three procoagulant complexes (extrinsic factor Xase, intrinsic factor Xase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each membrane complex consists of a vitamin K–dependent serine protease (factor VIIa, factor IXa, factor Xa, or thrombin [IIa]) and a soluble or cell surface–associated cofactor (tissue factor [TF] factor VIIIa, factor Va, or thrombomodulin [TM]). Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate or substrates (factors IX, X, and II and protein C) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants and enhances reaction rates by 105- to 106-fold. *(Redrawn with permission from Mann KG: Dynamics of Hemostasis. Essex Junction, Vt., Haematologic Technologies, 2002.)*

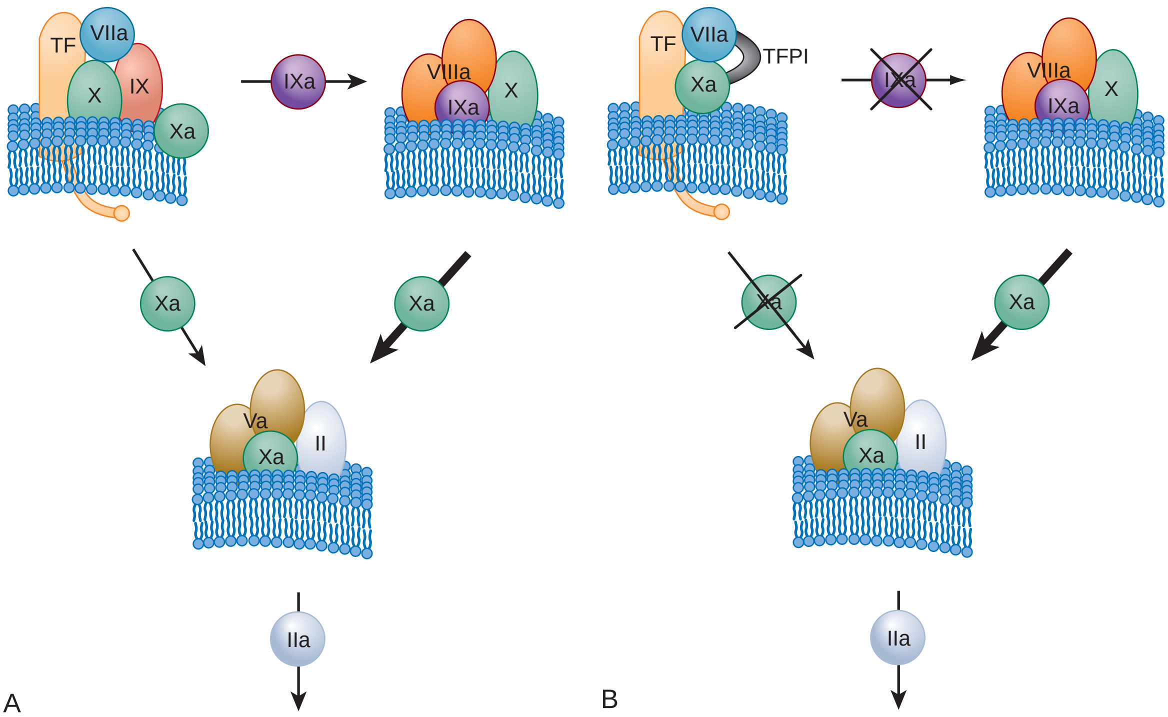

Figure 27-4 **A,** The factor Xa generated by the factor VIIa–tissue factor (TF) complex catalyzes the formation of a small amount of thrombin, which activates factors V and VIII and leads to the presentation of the intrinsic factor Xase (factor IXa-VIIIa) and prothrombinase (factor Xa-Va). At this point in the reaction, generation of factor IXa is cooperatively catalyzed by membrane-bound factor Xa and by factor VIIa–TF. The thick arrow representing generation of factor Xa by the intrinsic factor Xase illustrates the more efficient generation of factor Xa by this catalyst. **B,** The tissue factor pathway inhibitor (TFPI) interacts with the factor VIIa–TF–factor Xa product complex to block TF-initiated activation of both factor IX and X, thus leaving the factor IXaβ-VIIIa complex as the only viable catalyst for activation of factor X. *(Redrawn with permission from Mann KG: Dynamics of Hemostasis. Essex Junction, Vt., Haematologic Technologies, 2002.)*

by prothrombinase in 1 minute would be produced by factor Xa acting alone in 6 months. As a consequence, factor Xa is ineffective in hemostasis without the presentation of both factor Va and the platelet membrane binding sites on which prothrombinase is formed. The blood coagulation reaction can be described as occurring in three overlapped phases: initiation, propagation, and termination.

Initiation

The factor VIIa–TF–membrane complex (extrinsic factor Xase) (Fig. 27-4, *A*; also see Fig. 27-3) catalyzes the activation of both factor IX and factor X, the latter being the more efficient substrate.[7] Thus the initial product formed is factor Xa. Feedback cleavage of factor IX by membrane-bound factor Xa enhances the rate of generation of factor IXa in a cooperative process with the factor VIIa–TF complex.[9]

The initially formed, membrane-bound factor Xa activates small amounts of prothrombin to thrombin.[20] This initial activation of prothrombin provides the thrombin essential for acceleration of the hemostatic process by serving as the activator for platelets and the procofactors factor V[15] and factor VIII (see Fig. 27-1). Once factor VIIIa is formed, the factor IXa generated by the factor VIIa–TF complex combines with factor VIIIa on the activated platelet membrane to form the intrinsic factor Xase (see Figs. 27-3 and 27-4, *A*), which becomes the major activator of factor X. The factor IXa–factor VIIIa complex is 10^6-fold more active as a factor X activator and 50 times more efficient than the factor VIIa–TF complex in catalyzing activation of factor X (thus the bulk of factor Xa is ultimately produced by the factor IXa–factor VIIIa complex).

Propagation

As the reaction progresses, generation of factor Xa by the more active intrinsic factor Xase exceeds that of the extrinsic factor Xase complex.[21] In addition, the extrinsic factor Xase complex is subject to inhibition by TFPI[11] (Fig. 27-4, *B*). As a consequence, most (>90%) of factor Xa is ultimately produced by the factor VIIIa–factor IXa complex. In hemophilia A and hemophilia B, this amplification of factor Xa generation does not occur.[22] Factor Xa combines with factor Va on the activated platelet membrane receptors, and this factor Va–factor Xa prothrombinase catalyst (see Figs. 27-3 and 27-4) converts most prothrombin to thrombin. Prothrombinase is 300,000-fold more active than factor Xa alone in catalyzing activation of prothrombin.[17]

Termination

The same hemostatic process required for preventing leaks from the vasculature may also be life threatening when responsible for intravascular occlusion. Thus equally important to the hemostatic process are the stoichiometric and dynamic inhibitory systems, which block the presentation of thrombin. The sum of inhibitory functions is far in excess of the potential coagulant response. These inhibitory processes governed by TFPI, AT, and the protein C pathway act in synergy to provide activation thresholds, for which a minimum level of TF stimulation must be achieved before significant thrombin generation can occur.[23] The termination phase thus occurs throughout the reaction process.

Flow Regulation

Current data are consistent with the concept of a two-compartment model for regulation of the procoagulant response to a breach in a blood vessel (Fig. 27-5). Regulation of clotting in the extravascular space, apart from providing the initiating TF, is primarily passive and controlled by the availability of fresh blood, whereas regulation in the intravascular compartment is dynamic.

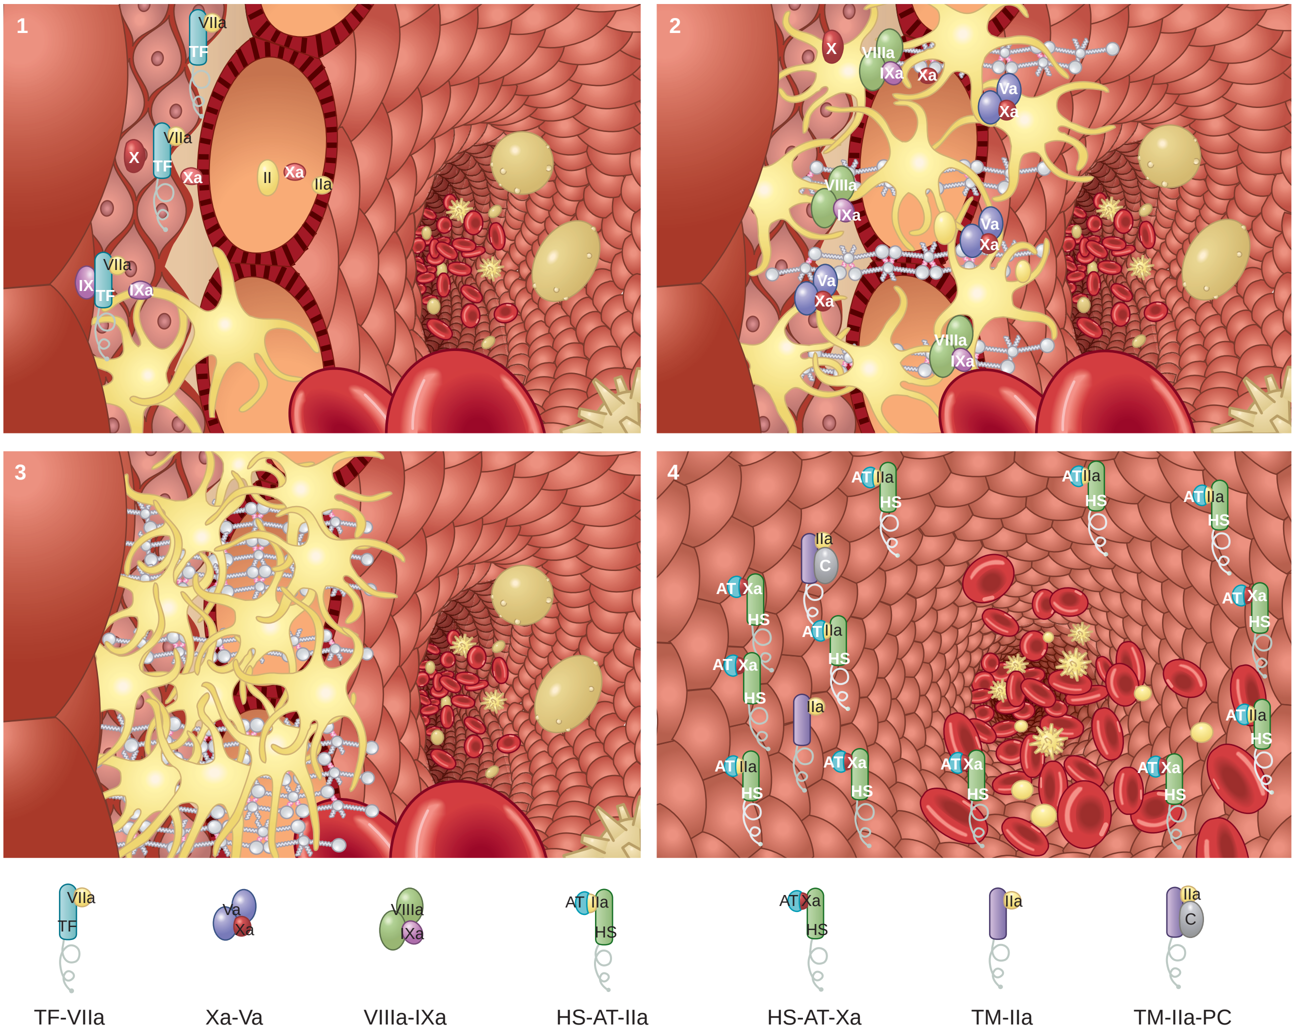

Figure 27-5 Schema of a two-compartment model of the regulation of tissue factor (TF)-initiated blood coagulation. A cross-section of a blood vessel showing the luminal space, endothelial cell layer, and extravascular region is presented at the site of a perforation. The blood coagulation process in response is depicted in four stages. TF–factor VIIa complex, TF-VIIa; prothrombinase complex, Xa-Va; intrinsic factor Xase, VIIIa-IXa; antithrombin (AT)–endothelial cell heparan sulfate (HS) proteoglycan complex bound to thrombin or factor Xa, HS-AT-(IIa or Xa); protein C (PC) bound to thrombomodulin-thrombin, TM-IIa-PC. Stage 1. Perforation results in delivery of blood and, with it, circulating factor VIIa and platelets to an extravascular space rich in membrane-bound TF. Platelets adhere to collagen and von Willebrand factor associated with the extravascular tissue, and TF binds factor VIIa, thereby initiating the process of activation of factors IX and X. Factor Xa activates small amounts of prothrombin to thrombin, which in turn activates more platelets and converts factors V and VIII to factors Va and VIIIa. Stage 2. The reaction is propagated by platelet-bound intrinsic factor Xase and prothrombinase, with the former being the principal generator of factor Xa. Initial clotting occurs and fibrin begins to fill in the void in cooperation with activated platelets. Stage 3. A barrier composed of activated platelets laden with procoagulant complexes and enmeshed in fibrin scaffolding is formed. The reaction in the now-filled perforation is terminated by consumption of reagent, which attenuates further generation of thrombin, but functional procoagulant enzyme complexes persist because they are protected from the dynamic inhibitory processes found on the intravascular face. Stage 4. View downstream of the perforation. Enzymes escaping from the plugged perforation are captured by AT-heparan complexes, and the protein C system is activated by binding of residual thrombin to endothelial cell thrombomodulin, thereby initiating the dynamic anticoagulant system. These intravascular processes work against occlusion of the vessel despite continuous resupply of reactants across the intravascular face of the thrombus. *(From Orfeo T, Butenas S, Brummel-Ziedens KE, Mann KG: The tissue factor requirement in blood coagulation.* J Biol Chem *280:42887-42896, 2005.)*

Mechanical disruption of a blood vessel results in the movement of blood to an environment where TF is exposed and platelets bind and are activated (see Fig. 27-5, *stage 1*). These events localize the initiating procoagulant reactions to blood now outside the vasculature, with adhesion and activation of platelets in this extravascular blood providing sufficient receptors and surfaces to support the propagation phase of thrombin generation (see Fig. 27-5, *stage 2*). This extravascular process rapidly becomes independent of TF as generation of thrombin becomes supplied by the intrinsic factor Xase and prothrombinase complexes. As long as new blood flows into this space, and fibrin formation and platelet aggregation have not achieved a sufficient barrier to stop flow, the system is open and the propagation phase of thrombin generation will continue. If blood ceases to move into the extravascular compartment, the system becomes closed, available prothrombin is consumed, and the complex enzymes are ultimately destroyed or sequestered into inactive complexes (see Fig. 27-5, *stage 3*). However, the stability of the prothrombin–activating potential incorporated into the platelet-rich thrombus and its localization in the extravascular space ensure that if the barrier springs a leak, robust generation of thrombin will begin immediately on contact and continue until consequent platelet activation and fibrin deposition reestablish a secure barrier.

Three mechanisms act to limit clot growth into the intravascular space (see Fig. 27-5, *stage 4*): thrombomodulin-dependent activation of protein C,[14] the presence of abundant AT, and the actively nonthrombogenic and nonadhesive surface of the vascular endothelium. Thus thrombin generation with consequent ongoing fibrin deposition and platelet activation is suppressed at the extravascular-intravascular boundary by these processes. In contrast, complexes at the extravascular side will remain relatively protected from APC and AT by the forming barrier and are therefore ready to respond to any leakage of blood.

The general properties of proteins of the blood coagulation proteome are summarized in Table 27-1. It has been stated that "a mouse is not a small furry human." A corollary is that an infant is not a tiny adult. This is especially true for the average plasma proteome concentration values for the newborn. These data are presented in parentheses in Table 27-1. Note that except for factor VIII and fibrinogen, most newborn functional protein concentrations are low relative to adult values (see Chapter 5).

THE VITAMIN K–DEPENDENT PROTEIN FAMILY

The Nobel Prize was awarded to Dam and Doisy in 1941 for their discovery of the fat-soluble vitamin K. Nearly simultaneously with the discovery of vitamin K, a naturally occurring antagonist, bishydroxycoumarin (dicumarol), was described. This antagonist was identified as a toxic agent in spoiled sweet clover that caused hemorrhage in cattle because of decreased thrombin formation. This agent was introduced as an anticoagulant in humans in 1941.[24]

Vitamin K, essential for the biosynthesis of clotting factors, contributes to the conversion of 10 to 13 glutamate residues to γ-carboxyglutamate residues (Gla). This posttranslational modification endows the vitamin K–dependent protein (VKDP) with Ca^{2+}-binding and membrane-binding qualities.[25] Gla formation is decreased or absent after treatment with coumarin derivatives.

The VKDPs (Fig. 27-6) can be divided into two classes: procoagulant (factors II, VII, IX, and X) and anticoagulant (protein C, protein S, and protein Z). The homology among these proteins is probably due to a common ancestral gene.[26] Each VKDP is composed of discreet domains characterized by highly conserved regions. The NH_2-terminal "Gla" domains (see Fig. 27-6) are followed by either kringle domains in prothrombin or epidermal growth factor (EGF)–like domains in factor VII, factor IX, factor X, protein C, protein S, and protein Z. Protein S contains four EGF domains followed by a sex hormone–binding domain (SHD). The serine protease domain for prothrombin, factor VII, factor IX, factor X, and protein C becomes functional after cleavage of specific peptide bonds. Protein S is not a serine protease precursor but is sensitive to thrombin cleavage. Protein Z contains a "pseudocatalytic domain" in the (COOH)-terminal but cannot function as a serine protease.

Synthesis of these proteins occurs primarily in the liver, although synthesis in other tissue has been reported. The plasma concentration of circulating VKDP varies 200-fold from approximately 100 μg/mL for prothrombin to 0.5 μg/mL for factor VII (see Table 27-1). Clearance rates of the VKDPs vary with their half-lives, from 6 hours (factor VII) to 2.5 days (prothrombin; see Table 27-1).

The VKDPs are synthesized as preproproteins and are modified posttranslationally at specific glutamates (γ-carboxylation) to form γ-carboxyglutamic acid (Gla).[25] Other modifications include β-hydroxylation at select aspartate and asparagine residues, tyrosine sulfation, and glycosylation. After synthesis of the single-chain precursors, the hydrophobic signal peptide directs each polypeptide to the endoplasmic reticulum. The propeptides, which play a role in docking vitamin K–dependent carboxylase,[27] are removed by an endoproteinase. For factor X and protein C, removal of an internal dipeptide or tripeptide converts them to their mature plasma two-chain zymogen forms.

The Gla domains constitute the first approximately 50 residues of the VKDPs (see Fig. 27-6). The negative charge elicited from the string of Gla residues (9 to 13) contributes to the binding of Ca^{2+} and generation of the conformation required for binding to anionic phospholipid membranes. In vivo, this surface is supplied by activated platelets or other blood cells in response to vascular damage through exposure of the phosphatidylserine-rich internal face of their cell membranes. Without vitamin K, or in the presence of vitamin K antagonists, the coagulation protein precursors are synthesized but not γ-carboxylated. In this form they are still secreted into plasma but display diminished function. The γ-carboxylation reaction is catalyzed by the enzyme γ-glutamyl carboxylase. This enzyme is located in the rough endoplasmic reticulum and requires the reduced form of vitamin K, oxygen, and

Figure 27-6 Schematic representation of the vitamin K–dependent proteins. The building blocks for these proteins are composed of Gla domains (9 to 13 Gla residues), followed by either kringle domains (K) in prothrombin or epidermal growth factor (EGF)–like domains in factors VII, IX, and X, protein C, protein S, and protein Z. Protein S contains a thrombin-sensitive region (TSR) before the EGF domain. The active site is contained within the serine protease domain for prothrombin, factors VII, IX, and X, and protein C and is functional upon cleavage at the activation site. Protein S is not a serine protease precursor and instead contains a sex hormone globulin binding (SHGB)–like domain in the COOH-terminal end. Protein Z contains a "pseudocatalytic domain" in the COOH-terminal end and does not function as a serine protease enzyme. For reference, the molecular weight for each protein is listed under its name, and disulfide bonds are illustrated as (-S-S-).

carbon dioxide[25] to convert glutamic acid residues to γ-carboxyglutamic acid.

Vitamin K_1 (phylloquinone) is primarily found in leafy green vegetables and vegetable oil. Additional K activity may be provided by vitamin K_2 (menaquinones) synthesized by intestinal gram-negative bacteria. Synthetic vitamin K_3 (menadione) has no intrinsic activity until it undergoes in vivo modification to the active menaquinone form. In vivo, vitamin K is recycled in a microsomal oxidation-reduction system for continued use in the γ-carboxylation reaction.[28,29] In order to perform the γ-carboxylation reaction, vitamin K has to be present in its reduced hydroquinone form. As the precursor proteins are carboxylated, vitamin K is oxidized to the epoxide. The epoxide in the presence of 2,3-epoxide reductase, with thiols being used as the reducing agent, yields the quinone form of vitamin K.[30] A subsequent reduced nicotinamide adenine dinucleotide phosphate (NADPH) or NADH-dependent quinone reductase reaction resynthesizes the hydroquinone form. The cycle can thus continue. Warfarin anticoagulant therapy blocks the process required for the regeneration of reduced hydroquinone vitamin K.[28,29] Because warfarin and other coumarin–derivative drugs indirectly affect carboxylation, they can be overcome with excess vitamin K.

The Gla domain is followed by two tandem EGF domains (EGF-1 and EGF-2) in factor VII, factor IX, factor X, and protein C and four EGF domains (EGF-1 to EGF-4) in protein S[31] (see Fig. 27-6). Each EGF-like domain consists of 40 to 50 amino acids, including 6 cysteine residues involved in disulfide bond formation. These domains are found widely distributed in extracellular and membrane proteins. Proteins containing these EGF-like domains are involved in blood coagulation, fibrinolysis, complement activation, connective tissue microfibril formation, and signal transduction.[32] The function of the EGF domain is still unclear. One hypothesis is that it serves as a spacer. There is a consistent elongation of the molecules of factors VII, IX, and X, protein C, and protein S. The distance between the membrane-binding Gla domain and the serine protease domain is crucial to placement of the active site in an appropriate position relative to the target peptide bond in its substrate.[33]

The serine protease domains (see Fig. 27-6) account for approximately half the mass of each protein. Peptide bond cleavage at specific sites converts the vitamin K–dependent zymogens to their active, chymotrypsin-like, serine protease forms. The mechanism of proteolysis by chymotrypsin involves a catalytic triad composed of Asp102, His57, and Ser195 (chymotrypsin numbering). The serine protease domains of all the Gla-containing factors are homologous members of the chymotrypsin family but cleave almost specifically at arginyl residues. However, unlike trypsin, which shows little specificity beyond the requirement for arginyl or lysyl residues at the cleavage site, the activated coagulation factors have extended substrate specificity pockets whereby only selected amino acid sequences are recognized by each protease. Thus despite the high degree of homology between the protease domains of protein C and factors II, VII, IX, and X, each of these factors has a highly specific function in coagulation. Some of this discrimination is mediated by surface loops, along with other domains distant from the substrate binding pocket termed exosites.

Factor VII (Proconvertin, Convertin)

The single-chain factor VII zymogen is activated to its two-chain protease form by cleavage of a single peptide bond between Arg152 and Ile153 (see Fig. 27-6). The mechanism for the initial activation of this zymogen is unclear. The resulting protease consists of an NH_2-terminal light chain linked by a single disulfide bond to a COOH-terminal heavy chain containing the catalytic domain. Factor VIIa has very poor catalytic efficiency without the presence of its cofactor TF.[34,35] Cleavage of factor VII to factor VIIa can be catalyzed by several proteases, including α-thrombin,[36] factor IXa,[37] factor Xa,[36] factor XIIa,[38] and factor VII–activating protease,[39] as well as by autoactivation by factor VIIa.[40] The active factor VIIa serine protease bound to TF forms the extrinsic factor Xase complex (see Fig. 27-3).

Factor VIIa, unlike other serine proteases of the coagulation cascade,[35] is not readily inhibited by circulating protease inhibitors, including the AT-heparin complex, unless bound to TF.[41,42] Thus regulation of TF expression is the primary means of controlling factor VIIa activity. Paradoxically, the zymogen factor VII (10 nM) is an effective competitor of factor VIIa (0.1 nM) for binding to TF. This competition downregulates the level of enzymatically active complex (factor VIIa–TF), thereby suppressing initiation of the clotting cascade. Once the extrinsic tenase complex activates factor X to factor Xa, TFPI can form a quaternary complex (factor VIIa–TF–factor Xa–TFPI) with no enzymatic activity[43] (see Fig. 27-4). Thus once assembled and functioning, the extrinsic tenase, along with its substrate factor Xa, is a target for inactivation through the action of TFPI.

Factor IX (Plasma Thromboplastin Component, Christmas Factor, Hemophilia B Factor)

Factor IX is a single-chain zymogen consisting of 415 amino acids organized with a Gla domain (12 Gla residues), two tandem EGF domains, an activation peptide region, and a serine protease domain (see Fig. 27-6). Glycosylation in the form of O-linked and N-linked oligosaccharides makes up 17% of the factor IX protein by weight.[44] Activation of factor IX is a two-stage process that requires cleavage at Arg145 and Arg180 and results in the release of a 35-residue activation peptide[45] (see Fig. 27-6). The physiologic activators of factor IX are either TF–factor VIIa (extrinsic tenase complex)[7] or factor XIa. The first cleavage at Arg145-Ala146 results in factor IXα. This cleavage has been shown to be important in its affinity for its cofactor factor VIIIa.[46] The second cleavage occurs at Arg180-Val181 and results in factor IXαβ, the active form, also referred to as *factor IX*a. Both cleavages are required for the biologic activity of factor IXa.[45] Plasma factor IXa is primarily inhibited by AT[47] (see Fig. 27-2). In vitro experiments conducted on phospholipid vesicles and cell membranes showed that protease nexin-2/amyloid β-protein precursor (PN2/APP) can also inhibit factor IXa.[48]

Factor X (Stuart Factor)

Factor X is synthesized in the liver and circulates as a two-chain molecule linked by a disulfide bond. The NH_2-terminal light chain consists of a Gla domain and two EGF-like domains (see Fig. 27-6). The COOH-terminal heavy chain consists of an activation peptide region and a catalytic (serine protease) domain. Factor X is activated by both the intrinsic and extrinsic factor Xases (see Figs. 27-1 and 27-3) by cleavage at Arg194-Ile195 (see Fig. 27-6). A 52–amino acid activation peptide is released. The resulting catalytic serine protease, factor Xa, is composed of a light chain and a disulfide-linked heavy chain. Factor X has to be bound to the membrane before activation.[19] Factor Xa participates in forming the prothrombinase complex (see Fig. 27-4).[17] The propagation phase of thrombin generation is catalyzed principally by factor Xa generated via the intrinsic tenase complex (see Fig. 27-3), which activates factor X at a 50- to 100-fold higher rate than the extrinsic tenase complex does.[9] The factor Xa active site associates with the COOH-terminus of TFPI.[49] The factor Xa–TFPI complex rapidly inactivates TF–factor VIIa to form a stable quaternary complex, TF–factor VIIa–TFPI–factor Xa.[49] Factor Xa is inhibited by AT[50] but only poorly when in the prothrombinase complex.[51]

Factor II (Prothrombin)

Prothrombin is the single-chain precursor of factor IIa (thrombin), the key enzyme in blood coagulation. The zymogen prothrombin is the most abundant of the plasma VKDPs and circulates in plasma at a mean concentration of 1.4 μM, or 100 μg/mL[52] (see Table 27-1). Prothrombin is synthesized primarily in the liver. Low levels of prothrombin expression have also been identified in other tissues, including the brain, diaphragm, stomach, kidney, spleen, intestine, uterus, placenta, and adrenal gland. Removal of the 43–amino acid propeptide generates the mature protein of 579 amino acids. An NH_2-terminal Gla domain is followed by two kringle domains and the serine protease precursor domain (see Fig. 27-6). Kringles have been identified as common motifs in many plasma proteins, including prothrombin, plasminogen, tissue plasminogen activator, urokinase, factor XII, and apolipoprotein(a).[53] The kringle 1 domain may interact with factor Va,[54] although kringle 2 appears to be the primary region mediating interaction with factor Va to form the prothrombinase complex.[55] This latter interaction may initiate conformational changes that make reaction sites accessible for enzymatic cleavage of prothrombin.[56] The NH_2-terminal Gla domain and the first kringle domain together are referred to as *prothrombin fragment 1*, with the kringle 2 domain being located in prothrombin fragment 2. The sequence of the enzyme α-thrombin is contained within prethrombin 2.

Activation of prothrombin by prothrombinase proceeds through an initial cleavage of prothrombin at Arg320-Ile321, which gives rise to meizothrombin, a two-chain disulfide-linked molecule (see Fig. 27-6). Meizothrombin expresses some of the activities of α-thrombin. However, the fibrinogen clotting ability of meizothrombin is impaired in comparison to that of α-thrombin.[57] Meizothrombin is subsequently cleaved at Arg271-Thr272 to yield the NH_2-terminal half of the molecule (prothrombin fragment 1.2) and α-thrombin. α-Thrombin consists of an NH_2-terminal 49-residue A-chain disulfide linked to a COOH-terminal 259-residue B chain containing the catalytic triad.

An alternative cleavage pathway occurs when factor Xa independently acts on prothrombin. In the presence of factor Xa and Ca^{2+}, the initial cleavage occurs at Arg271-Thr272 and gives rise to prothrombin fragment 1.2 and prethrombin 2. Subsequent cleavage at Arg320 in prethrombin 2 yields α-thrombin. Prothrombin fragment 1.2 remains noncovalently associated with α-thrombin.[58] In contrast to other VKDPs, the phospholipid-binding Gla region is not covalently attached to the serine protease domain after cleavage of prothrombin to thrombin.

α-Thrombin is the central enzyme in blood coagulation in that it contributes to reactions at all levels, thereby allowing overall maintenance of vascular integrity. Its premier role in hemostasis results in platelet-fibrin clot formation.[59] However, the events that lead up to and beyond fibrin formation also involve protein cleavage by α-thrombin, as well as activating platelets,[60,61] factor VII,[36] factor V,[15] factor VIII,[62] factor XI,[8] and factor XIII. The contributions of α-thrombin also extend to anticoagulant and fibrinolytic reactions, including activation of protein C and thrombin-activatable fibrinolysis inhibitor (TAFI).[63]

The stable form of human α-thrombin possesses at least five distinct binding sites for substrates, inhibitors, cofactors, apolar molecules, and sodium ions (Na^+).[64] Exosite I, the fibrinogen binding site, is an electropositive anion binding site distinct from, but acting in concert with, the active site of the α-thrombin molecule. In addition to fibrinogen, exosite I also recognizes the COOH-terminal domain of hirudin, the hirudin-like region of PAR-1, and the fifth and sixth EGF-like domains of thrombomodulin.[64]

Many of the effects of α-thrombin on platelets and cells are elicited through the interaction of α-thrombin with receptor molecules, with α-thrombin binding to a receptor and initiating a signal transduction mechanism. The interaction between α-thrombin and the human platelet thrombin receptor PAR-1, however, is characterized by a more unusual mechanism in which the receptor is also a substrate for α-thrombin.[65] α-Thrombin cleaves the extracellular region of the receptor and produces a "tethered ligand." The new NH_2-terminus binds back to and activates the receptor.[65,66] Two additional α-thrombin receptors homologous to PAR-1, PAR-3, and PAR-4 have been identified. α-Thrombin's role continues beyond hemostasis into the realm of tissue repair and the remodeling phase necessary to regenerate damaged vascular tissue. α-Thrombin is a potent mitogen[67] and stimulates cell division in macrophages,[68] smooth muscle cells,[69] and endothelial cells.[70]

Protein C (Autoprothrombin II-A)

Protein C circulates as a heterodimer consisting of disulfide-linked heavy and light chains[71] (see Fig. 27-6). However, approximately 5% to 10% of circulating protein C is in the single-chain form. The NH_2-terminal light chain contains the Gla domain and a hydrophobic region that connects the Gla domain to two EGF domains. The COOH-terminal heavy chain contains the serine protease domain.[72] Cleavage at Arg169-Leu170 releases the activation peptide from the heavy chain to generate the enzyme. Although the α-thrombin–thrombomodulin complex is probably the major physiologic activator of protein C,[73] other potential activators include plasmin and factor Xa.[72] The half-life of protein C (8 to 10 hours; see Table 27-1) is markedly shorter than the half-life of other members of the VKDP family, which is probably the basis of the transient hypercoagulable state that may occur subsequent to the administration of coumarin-based anticoagulants.

The anticoagulant role of the dynamic protein C inhibitory pathway is proteolytic inactivation of factor Va. APC inactivates factor Va via a sequential series of proteolytic cleavages and thus inhibits the generation of α-thrombin.[74] APC also cleaves and inactivates factor VIIIa, although the spontaneous dissociation/inactivation of factor VIIIa is probably the physiologic regulator of factor Xa generation.[75] Complete inactivation of factor Va by APC requires an anionic phospholipid surface, and rates of inactivation of factors Va and VIIIa by APC have been reported to be enhanced by protein S.[76,77] APC also has profibrinolytic effects associated with decreased activation of TAFI. TAFI is activated by the α-thrombin–thrombomodulin complex and acts to prolong clot lysis. Cleavage of factor Va by APC inhibits α-thrombin generation, thus reducing α-thrombin–thrombomodulin–mediated TAFI activation.[78]

Protein C activation and APC activity are controlled on several levels. The endothelial cell protein C receptor (EPCR) provides cell-specific binding sites for both protein C and APC.[79] Inflammatory agents such as endotoxin, interleukin-1β (IL-1β), tumor necrosis factor-β (TNF-β), and TNF-α upregulate protein C activation on endothelial cells.[80-82] TNF-α downregulates thrombomodulin on the endothelial cell surface.[82] There are multiple other factors that downregulate thrombomodulin as well. APC activity is further regulated by the protein C inhibitor, plasminogen activator inhibitor 3 (PAI-3).[83]

Protein S

Protein S is a VDKP that is not a serine protease precursor. Approximately 40% of protein S circulates in the free form, and the remaining 60% circulates as a 1 : 1 complex with C4b-binding protein (C4bBP), a regulatory protein of the complement system.[84] The precise function of protein S in the protein C inhibitory pathway is controversial. Protein S is thought to function as a cofactor for APC in the inactivation of factors Va and VIIIa.[85-87] Protein S has also been reported to bind to factor Xa,[88] factor VIII,[89] and factor Va[90] and compete for prothrombinase binding sites on the membrane surface.[91] The C4bBP–protein S complex may inhibit factor X activation as well.[92] Protein S may have other roles apart from anticoagulation.[93] α-Thrombin cleavage of protein S inhibits the ability of protein S to act as a cofactor for APC.[94] The anticoagulant activity of protein S is also neutralized when bound to C4bBP.[84,92]

Protein Z

Protein Z is an enzymatically inactive homologue of factors VII, IX, and X and protein C.[95,96] Protein Z circulates in plasma in a complex with protein Z–dependent protease inhibitor (ZPI). ZPI is a 72-kD member of the serpin superfamily. However, like protein S, protein Z does not function as a protease. Although the COOH-terminus contains a homologue to the catalytic domains present in serine protease zymogens, the catalytic triad is not present.[96] The function of protein Z in vivo is unclear. Thrombosis is observed in mice when factor V Leiden is protein Z deficient.[97]

FACTOR XI, THE CONTACT PATHWAY CROSSOVER (PLASMA THROMBOPLASTIN ANTECEDENT)

Factor XI is a substrate for thrombin (see Fig. 27-1) and, when cleaved to factor XIa, activates factor IX.[8] Factor XI circulates as a homodimer in complex with HMWK[98] (see Table 27-1) and is also found in platelets.[99] Unlike other members of the accessory or contact pathway, factor XIa has a role in coagulation as part of a positive feedback loop that enhances the generation of α-thrombin.[8] Plasma factor XI accounts for most of the factor XI activity in humans and is a disulfide-linked homodimer (see Table 27-1). The NH_2-terminus contains four tandem sequences termed Apple domains (Apple 1 to Apple 4), followed by the COOH-terminal catalytic domain. The Apple domains are homologous to the Apple domains in human plasma prekallikrein.[100] The Apple domains mediate factor XI dimerization, as well as binding to its various cofactors and substrates.[98,101]

Plasma factor XI is cleaved at an internal Arg369-Ile370 bond to yield a disulfide-linked two-chain activated serine protease. The factor XI homodimer yields two disulfide-linked heavy chains containing the Apple domains and two light chains containing the active sites.[102,103] Activation of factor XI can be accomplished by factor XIIa and α-thrombin and by autoactivation by factor XIa itself. Activation of factor XI by factor XIIa requires HMWK and an anionic surface. However, deficiencies of factor XII and HMWK do not result in bleeding diatheses, whereas factor XI deficiency is associated with hemorrhage. This suggests that factor XIIa–dependent activation of factor XI as part of the contact pathway is not likely to be the primary route of factor XIa generation in hemostasis. The physiologically relevant pathway for activation of factor XI in coagulation is believed to involve α-thrombin.[8,104] Subsequent to activation, factor XIa remains bound to the surface. Factor XIa is a trypsin-like serine protease that cleaves and activates factor IX in a Ca^{2+}-dependent fashion.[105,106] Factor IXa is the enzyme component of the intrinsic tenase complex that provides the burst of factor Xa needed for normal coagulation. As part of a positive feedback loop, α-thrombin activates factor XI. In turn, factor XIa generates factor IXa, which leads to the high levels of factor Xa that ensure efficient generation of α-thrombin.[8]

Factor XIa is regulated by four serine protease inhibitors: AT, α_1-protease inhibitor, C1 inhibitor, and α_2-antiplasmin.[107-109] Factor XIa is also reported to be inhibited by PAI-1 and protein C inhibitor.[110] In addition, platelets secrete several factor XIa inhibitors,[111] including PN2.[112]

COFACTOR PROTEINS

There are two categories of procoagulant cofactor proteins: the plasma-derived soluble procofactors factor V and factor VIII (the latter in complex with its circulating carrier von Willebrand factor [VWF]) and the cell-associated cofactors TF and thrombomodulin. Factors V and VIII are highly homologous (40% identity). These cell-associated cofactors are single-chain transmembrane proteins, each composed of extracellular, transmembrane, and cytoplasmic domains.

Factor V (Labile Factor)

The procofactors factors VIII and V are organized into discrete structural domains (Fig. 27-7). Factor V was initially recognized as an unstable plasma component necessary for the generation of α-thrombin.[113] Most factor V circulates in plasma (see Table 27-1), but 18% to 25% of the total factor V is present in platelet alpha granules.[114]

The intron-exon structure of the factor V and factor VIII genes is quite similar, and the genes probably evolved from a common ancestor. The liver appears to be the

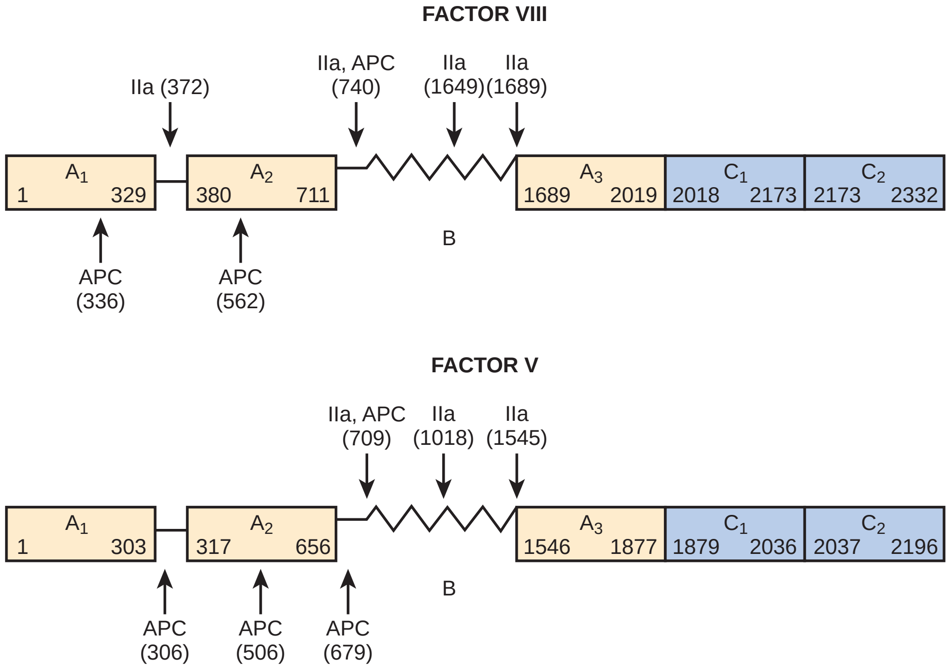

Figure 27-7 Soluble cofactor domain structures (factors VIII and V). The domain structures (A1-A2-A3-B-C1-C2) are bracketed by the beginning and ending amino acid residue. α-Thrombin (IIa) and activated protein C (APC)/factor Xa cleavage sites are shown with *vertical arrows*.

primary site of factor V biosynthesis. Although human megakaryocytes have also been reported to express factor V,[115] platelet factor V appears to be primarily derived from plasma factor V.[116] Human factor V is composed of A1-A2 domains, a central B domain, and a COOH-terminal light-chain precursor (A3-C1-C2 domains). The A domains are homologous to those found in factor VIII and ceruloplasmin; the C domains are homologous to the slime mold protein discoidin. Like factor VIII and ceruloplasmin, factor V is a copper-binding protein.[117]

Factor V undergoes extensive posttranslational modification, including phosphorylation, sulfation, and glycosylation. Phosphorylation at Ser692 affects the rate of inactivation of factor Va by APC.[118] The tyrosine sulfation status of factor V has also been related to its function.[119] Carbohydrate accounts for 13% to 25% of the mass of factor V and about 50% of the mass of the B region.[120] Differential glycosylation of Asn2182 in the C2 domain is reported to be responsible for the factor V1 and factor V2 variants observed in plasma.[121] Factors Va1 and Va2 appear to also be distinguished by functional differences.

The procofactor factor V does not bind factor Xa and is essentially completely inactive.[17] Limited proteolysis of the factor V molecule yields the active cofactor. α-Thrombin cleaves factor V at Arg709, Arg1018, and Arg1545 (see Fig. 27-7). The α-thrombin–generated form of factor Va is a heterodimer consisting of an NH_2-terminal heavy chain (A1-A2 domains) linked noncovalently to a COOH-terminal light chain (A3-C1-C2 domains).[122-125] The B domain is excised during proteolytic activation.[126] Factor Xa also cleaves factor V to produce a molecule similar to the factor Va produced by α-thrombin cleavage.[127] In addition, other enzymes may fully or partially activate factor V.[128] Factor Va functions both as a receptor for factor Xa and as a positive modulator of the catalytic potential of factor Xa in the prothrombinase complex. The cofactor forms at least part of the receptor for factor Xa on platelets and serves to anchor factor Xa to the membrane surface.[15,16,62]

Factor Va is downregulated via proteolytic inactivation by APC. APC cleaves factor Va at three sites: Arg506, Arg306, and Arg679. Initial factor Va cleavage occurs at Arg506. Subsequently, the membrane-dependent cleavage at Arg306 results in dissociation of the A2 domain as two fragments and complete loss of factor Va cofactor activity. An additional APC-mediated cleavage of factor Va fragments occurs at Arg679. The importance of this regulatory mechanism is demonstrated by the "APC resistance" syndrome associated with factor V Leiden.[129,130] The factor V Leiden Arg506→Gln mutation eliminates the first and most rapid of the sequential inactivating cleavages by APC. Factor Va Leiden thus retains cofactor activity and continues to promote α-thrombin generation for an extended period. Ultimately, inactivation of factor Va Leiden by cleavage of the Arg306 bond does occur, but at a markedly slower rate.[131]

Factor VIII (Antihemophilic Factor, Factor VIII:C)

Factor VIII circulates in plasma in complex with the large multimeric protein VWF. The ratio of factor VIII to VWF is in the range of 1 molecule of factor VIII to 50 to 100 molecules of VWF monomeric units. VWF acts to transport and stabilize plasma factor VIII. Factor VIII in complex with VWF has a plasma half-life of approximately 12 hours, whereas factor VIII alone undergoes rapid clearance and has a half-life of approximately 2 hours.[132,133] The liver and spleen are thought to be the primary sites of factor VIII biosynthesis.[134]

Though synthesized as a 2351–amino acid single-chain protein, human plasma factor VIII undergoes significant proteolytic processing that results in a heterogeneous collection of forms. The heterogeneity in molecular weight is due to proteolysis of the protein in circulation or processing before secretion (or both). The initial synthesized product is composed of three A domains, two C domains, and a connecting B domain (see Fig. 27-7). The secreted factor VIII molecule is a two-chain heterodimer as a result of intracellular proteolysis at the B-A3 junction. Additional cleavages within the B chain yield a heavy chain of A1-A2 domains linked to B fragments of variable length.[135] The B domain is highly glycosylated and contains 18 of the 25 potential N-linked glycosylation sites in factor VIII. Activation by α-thrombin involves cleavage at Arg372 (the A1-A2 junction), Arg740 (the A2-B junction), and Arg1689 in the light chain (the B-A3 junction) and excision of the remnant of the B domain. The resulting molecule contains three separate polypeptide chains: a light chain (A3-C1-C2) bound to the NH_2-derived heavy chain and the noncovalently associated A2 region of the heavy chain. Factor VIIIa is an unstable molecule, with dissociation of the A2 domain leading to spontaneous inactivation.[136] Factor VIII shares homology with the copper ion–binding protein ceruloplasmin and contains a reduced copper ion (Cu^+) binding site in the A1 domain that is important for function.[137] A specific VWF binding site has been identified between residues 1673 and 1684 of the factor VIII light chain.[138] The VWF binding site is removed from factor VIII during activation by α-thrombin cleavage at Arg1689. High-affinity factor IXa binding is observed for the factor VIIIa light-chain A3 domain.[139] Sulfation of several tyrosine residues in factor VIII is also important for function.[140]

The cofactor factor VIIIa binds factor IXa with Ca^{2+} (and membrane) to form the intrinsic factor Xase complex (see Fig. 27-3). The intrinsic factor Xase complex catalyzes the activation of factor X at a rate orders of magnitude greater than the enzyme factor IXa alone[18] (see Fig. 27-4). Factor Xa generated via the intrinsic factor Xase complex is the primary contributor of the factor Xa required for the propagation phase of thrombin generation.[21] In hemophilia A or B the intrinsic factor Xase complex cannot be formed, and the factor Xa levels required to induce the propagation phase of thrombin generation are not produced,[22] thereby resulting in lethargic thrombin formation and poor clot formation (see Fig. 27-5).

The spontaneous loss of factor VIIIa function is primarily a consequence of dissociation of the A2 subunit from the heterotrimer. Once the A2 subunit is displaced, factor VIIIa loses cofactor function. Dissociation occurs rapidly under physiologic conditions. The factor IXa–membrane complex interactions stabilize factor VIIIa and thus delay dissociation of the heterotrimer and prolong the transient activity of factor VIIIa.[141] Factor VIIIa is also regulated by limited proteolysis. Factor IXa cleaves the A1 subunit of factor VIIIa at Arg336 and eliminates factor VIIIa function.[142] APC is a key anticoagulant enzyme that likewise cleaves the A1 subunit at Arg336. APC also cleaves the A2 subunit of factor VIIIa at Arg562.[143] These APC cleavages occur sequentially, with the A1 cleavage occurring first and the A2 cleavage second.[144] Factor IXa protects factor VIIIa from APC cleavage at Arg562; however, protein S blocks the protective effect.[145] Although factor VIIIa is proteolytically inactivated by a number of enzymes, spontaneous dissociation appears to be the key regulator of cofactor function.

von Willebrand Factor (Ristocetin Cofactor)

VWF is a multifunctional protein with several key roles in coagulation. VWF circulates in plasma and is also contained in the alpha granules of human platelets.[146] In addition, it is known for its role in ristocetin-induced platelet aggregation (see Chapters 26 and 31). VWF is expressed by endothelial cells and megakaryocytes and is stored in Weibel-Palade bodies in endothelial cells and in alpha granules in platelets.[147,148] VWF is a large adhesive glycoprotein that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers (see Chapter 31). The disulfide-linked multimers range in size from dimers, $M_r = 600{,}000$, to extremely large multimers consisting of more than 20 million Daltons. VWF has binding sites for factor VIII, heparin, collagen, platelet glycoprotein Ib, and platelet glycoprotein IIb-IIIa.[149] Plasma VWF transports and stabilizes factor VIII and protects it from inactivation by APC,[87] thus significantly prolonging the half-life of factor VIII in circulation.[133] VWF also acts as a bridge between platelets and promotes platelet aggregation. The primary platelet binding site for VWF is the glycoprotein Ib-IX-V receptor complex (see Chapters 26 and 31). Endothelial cells secrete VWF multimers that are larger than those found circulating in plasma. The function of these large multimeric forms of VWF is to bind to and agglutinate blood platelets under high shear rates. These large multimers of VWF are degraded by a specific metalloproteinase, ADAMTS-13.[150]

Tissue Factor (Tissue Thromboplastin Cd142 and Coagulation Factor III)

TF and thrombomodulin (Fig. 27-8) are intrinsic membrane proteins that are essential cofactors for factor VIIa and thrombin, respectively. They share no homology at the molecular level. TF is a transmembrane protein that functions as a cofactor for factor VIIa in the extrinsic factor Xase complex. In the absence of injury or stimulation, active TF is not ordinarily expressed on cellular surfaces in direct contact with circulating blood. Presentation of TF to the circulation is the event that triggers the primary procoagulant pathway of coagulation (see Fig. 27-1). Expression of TF can be induced in a number of cultured cell types. Monocytic cells and monocytes isolated from peripheral blood also express TF when stimulated by bacterial endotoxin or other proinflammatory agents. There is little or no detectable TF expression on unstimulated endothelial cells in vivo, although certain conditions such as sepsis, placental villitis, and graft rejection induce endothelial TF expression.[151] The mechanism governing TF expression under nonpathologic conditions is unknown.

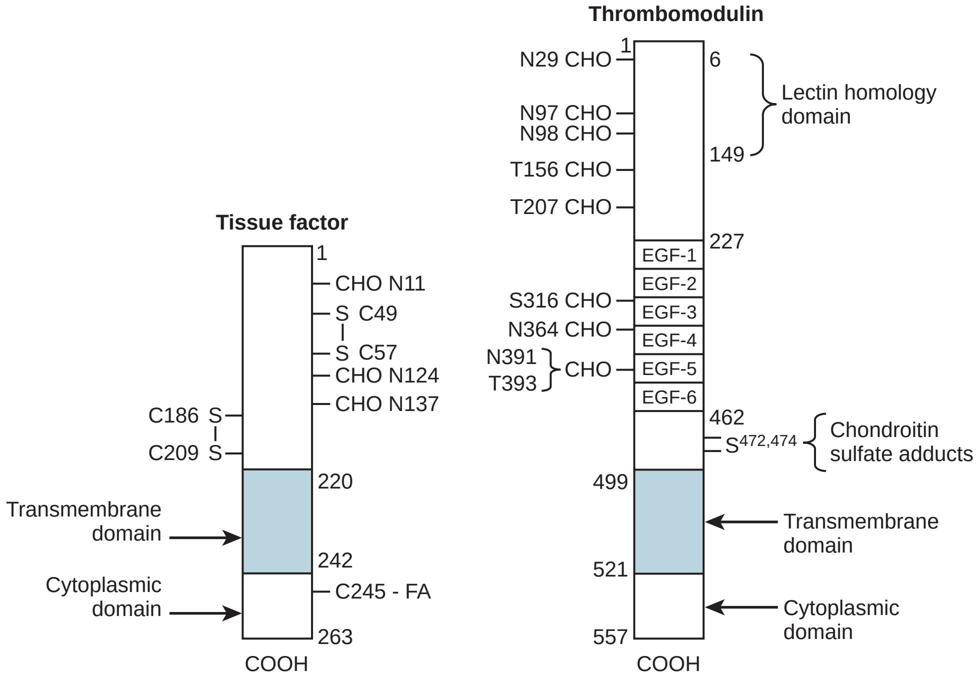

Figure 27-8 Transmembrane cofactors. Tissue factor is composed of an extracellular domain (residues 1 to 219), a transmembrane domain (residues 220 to 242), and a cytoplasmic domain (residues 243 to 263). Two disulfide bonds (S-S) and the sites of the three carbohydrate moieties (CHO) are identified by amino acid residue. One cysteine (C245) contains a thiol ester linkage to a fatty acid. Thrombomodulin is composed of five distinct domains. The domain structures are a lectin-like domain (residues 6 to 149), a domain containing six epidermal growth factor (EGF)-like regions (residues 227 to 462), a small extracellular domain rich in threonine and serine residues (two have been identified as sites of chondroitin sulfate adducts: S472 and S474), a membrane-spanning region (residues 499 to 521), and a cytoplasmic tail (residues 522 to 557). There are nine known glycosylation sites (CHO) on the thrombomodulin molecule.

TF is a member of the class 2 cytokine receptor superfamily and a type I integral membrane protein. The NH_2-terminus of TF (residues 1 to 219) is extracellular, whereas the COOH-terminus of the protein is intracellular (residues 243 to 263). TF also contains a hydrophobic membrane-spanning domain (see Fig. 27-8). This domain appears to function as an anchor for TF in the membrane.[152] The NH_2-terminal domain of TF is composed of two fibronectin type III domains and is glycosylated. The COOH-terminal cytoplasmic domain is quite short, and its function is unclear because deletion of this domain has no significant effect on TF procoagulant activity.[152]

TF can bind either factor VII or factor VIIa to form a high-affinity 1:1 complex. Once bound to TF, the zymogen factor VII may be converted to factor VIIa via limited proteolysis.[153,154] The TF–factor VIIa or extrinsic tenase complex activates both factor IX and factor X. When TF is exposed or expressed subsequent to vascular perturbation, the low levels of circulating factor VIIa bind to TF, and the extrinsic factor Xase complex triggers the procoagulant cascade (see Fig. 27-4, *A*).[9,155]

In the absence of TF, factor VIIa is relatively inert. TF alters the active site of factor VIIa, thus functioning as an allosteric activator of the enzyme.[40,155] Although the cofactor is necessary for enzymatic activity, formation of the TF–factor VIIa complex does not require an anionic phospholipid membrane surface as do the other procoagulant complexes. The membrane dependency of the extrinsic factor Xase complex function in factor X and factor IX activation arises from membrane-mediated substrate delivery. Both factors X and IX bind to the membrane surface for efficient two-dimensional transfer to the extrinsic factor Xase complex.

TF is primarily regulated through availability. In normal hemostasis, the commonly accepted source of functional TF is through exposure of the subendothelium after vascular perforation. However, controversy has arisen regarding the sources and presentation of active TF and whether functional TF circulates in blood.[156,157] Once the TF–factor VIIa complex is formed in the vicinity of an injury, the extrinsic tenase activity is modulated by TFPI and AT.

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein that is constitutively expressed on the surface of vascular endothelial cells (see Fig. 27-8). Thrombomodulin is a high-affinity receptor for α-thrombin and acts as a cofactor for the α-thrombin–dependent activation of protein C and TAFI. Thrombomodulin expression has been reported in a variety of cell types, including vascular endothelial cells.[158] The activity of thrombomodulin on the surface of endothelial cells is decreased by inflammatory cytokines, which may contribute to the hypercoagulation characteristic of inflammatory states. Homozygous thrombomodulin-deficient mice die in utero before formation of the cardiovascular system, thus suggesting a potential role for thrombomodulin in mammalian development.[159]

The domain structure of thrombomodulin is depicted in Figure 27-8. The fifth and sixth EGF domains support α-thrombin association.[160] The presence of chondroitin sulfate increases the affinity for α-thrombin 10-fold.[161] The chondroitin sulfate moiety also enhances inactivation of α-thrombin by AT[162] and modulates protein C activation.[161,162] The O-linked sugar domain of thrombomodulin is required for generation of APC on cellular surfaces. This domain is extended and rigid and probably functions to elevate α-thrombin from the membrane surface.

Production of APC by the α-thrombin–thrombomodulin complex is approximately 1000 times faster than equivalent concentrations of protein C and α-thrombin. Once bound to thrombomodulin, α-thrombin's procoagulant activities are neutralized. The high-affinity α-thrombin–thrombomodulin interaction is mediated mainly by exosite I on the α-thrombin molecule. Exosite I also binds fibrinogen, and interaction of α-thrombin with thrombomodulin therefore blocks fibrinogen binding and cleavage. In addition, thrombomodulin induces conformational changes in α-thrombin.[163,164] The changes that occur upon interaction of α-thrombin with thrombomodulin reduce the ability of α-thrombin to generate fibrin, activate factor V, or activate platelets[165] and increase the inactivation of α-thrombin by AT.[165] Thus the α-thrombin–thrombomodulin complex, or protein case (see Fig. 27-3), functions in an anticoagulant and antifibrinolytic capacity.

THE INTRINSIC (ACCESSORY) PATHWAY FACTORS

The procoagulant proteins that make up the intrinsic or accessory pathway consist of factor XII, plasma prekallikrein, HMWK, and factor XI. These proteins are responsible for the contact (intrinsic) activation of blood coagulation (see Fig. 27-1).

Factor XII (Hageman Factor, Contact Factor)

Factor XII plays a primary role in initiation of the contact or intrinsic pathway of coagulation upon binding with substances such as glass or kaolin. The contact pathway is the basis for the APTT clotting assay. Deficiency of factor XII is not associated with bleeding abnormalities, and therefore the precise role of factor XII in hemostasis is unclear, although the components of the contact pathway may provide a link between coagulation and inflammation.

The factor XII molecule is composed of two domains: a NH_2-terminal heavy chain and a COOH-terminal light chain. The heavy chain contains fibronectin type I and type II domains, two EGF-like domains, a kringle domain, and a proline-rich region. The light chain contains the serine protease catalytic domain, a region homologous to the B chain of the enzyme plasmin.

Factor XII undergoes autoactivation upon interaction with negatively charged surfaces such as glass, kaolin, dextran sulfate, ellagic acid, celite, or bismuth subgallate.[166] These are probably artifactual triggers, and the physiologic activator is unknown. Although factor XII associates with many physiologically relevant anionic surfaces, including negatively charged phospholipids, the autoactivation of factor XII induced by these surfaces in vitro does not appear to represent the mechanism of factor XII activation in vivo.[167]

Factor XIIa, prekallikrein, and HMWK form a complex on anionic phospholipids of the cell membrane, and prekallikrein is cleaved to kallikrein. Kallikrein activates factor XII by cleavage at Arg353-Val354 to generate an 80-kD two-chain enzyme, α-factor XIIa (factor XIIa). This cleavage is essential for exposure of the active site in factor XIIa.[168]

Factor XIIa activates factor XI and prekallikrein by mechanisms dependent on anionic surfaces and the cofactor HMWK. Factor XIIa also activates the C1 component of the complement system,[169] downregulates the Fc receptor on monocytes and macrophages,[170] and stimulates neutrophils.[171] Although these roles have no apparent impact on normal coagulation, factor XII/XIIa may be an important link between coagulation and inflammation. Factor XIIa also activates plasminogen to plasmin, thereby linking the contact pathway to fibrinolysis.[172]

Plasma Prekallikrein (Fletcher Factor)

Plasma prekallikrein deficiency is rare and is not associated with a hemostatic defect. Approximately 75% of plasma prekallikrein circulates in a noncovalent complex with HMWK,[173] and the remaining 25% circulates as free prekallikrein. Prekallikrein contains four tandemly repeated Apple domains in the NH_2-terminal portion of the molecule that are highly homologous to the Apple domains of factor XI. Prekallikrein is activated by factor XIIa in complex with the cofactor HMWK on an anionic surface (see Fig. 27-1). The enzyme kallikrein is a two-chain molecule composed of an NH_2-terminal heavy chain containing the four Apple domains and a COOH-terminal light chain containing the active site.[174]

Kallikrein is a member of the trypsin family of serine proteases. In the presence of an appropriate anionic surface and the cofactor HMWK, kallikrein activates factor XII to factor XIIa and proteolyses factor XIIa to β-factor XIIa. Kallikrein also undergoes autoproteolysis to yield β-kallikrein.[175] Enzyme activity is significantly reduced upon conversion of kallikrein to β-kallikrein. Kallikrein cleaves HMWK at two sites to generate the vasoactive nonapeptide bradykinin, a potent vasodilator. Kallikrein is also an activator of fibrinolytic zymogens and converts both plasminogen to plasmin and pro–urokinase plasminogen activator (pro-uPA) to uPA.[176] In addition, kallikrein has been reported to activate neutrophils and stimulate release of elastase as part of the hemostatic and inflammatory responses.[177] C1 inhibitor and α_2-macroglobulin are the major inhibitors of kallikrein.[178]

High–Molecular-Weight Kininogen (Fitzgerald Factor, Williams Factor)

HMWK acts as a cofactor for the activation of factor XII and prekallikrein and is the precursor of the vasoactive peptide bradykinin. A second form of kininogen, low–molecular-weight (LMWK), is also found in plasma. LMWK can be cleaved to yield bradykinin but has no procoagulant activity. Deficiencies of HMWK and LMWK are rare and are not associated with bleeding diatheses.[179] The major established function of the kininogens is to serve as a source of bradykinin and thereby contribute to a number of vascular events regulated by bradykinin.

The two forms of kininogen, HMWK and LMWK, are the products of a single gene and are produced by alternative splicing.[180] The NH_2-terminal heavy chains of the two forms are identical and contain potent inhibitors of cysteine proteases such as calpain.[181] The central domain of both kininogens is the bradykinin region. The two forms of kininogen have different COOH-terminal light-chain regions. The light chain of HMWK contains binding sites for prekallikrein and factor XI.[182] Kallikrein, factor XIIa, and factor XIa cleave HMWK to release bradykinin. Kallikrein will also cleave LMWK to release bradykinin.

As noted earlier, the biologic significance of the contact pathway of coagulation is not established. In hemostasis, generation of factor XIa most likely proceeds via an α-thrombin–dependent pathway, and any factor XIa generated by the contact pathway would not have a measurable impact on coagulation. Release of bradykinin as a consequence of these activation events, however, does provide a key vasoactive agent with a variety of roles and directly links the contact pathway to vascular repair processes.

STOICHIOMETRIC INHIBITORS

In vivo, the hemostatic reaction is tightly regulated to ensure that adequate but limited levels of α-thrombin are generated. Two systems, one stoichiometric and one proteolytic, regulate the generation of thrombin. In the proteolytic system (described earlier), α-thrombin participates in its downregulation by binding to thrombomodulin on the vascular cell surface and converting protein C to APC. This anticoagulant serine protease cleaves factors Va and VIIIa, thereby eliminating thrombin generation. The stoichiometric inhibitors consist of the AT-heparin complex, which inhibits virtually all the procoagulant serine proteases, and TFPI, which targets the factor VIIa–TF–factor Xa complex and principally regulates the initiation phase of the blood coagulation process (see Fig. 27-2).

Tissue Factor Pathway Inhibitor (Extrinsic Pathway Inhibitor, Lipoprotein-Associated Coagulation Inhibitor)

TFPI is a multivalent protein that modulates TF-dependent coagulation by inhibiting the extrinsic tenase complex.[183] TFPI is expressed constitutively by cultured endothelial cells and consists of an acidic NH_2-terminal region, three tandem Kunitz-like serine protease inhibitor domains (K1 to K3), and a positively charged COOH-terminal region. The tandem Kunitz domains are essential for function.[184] Two variants of TFPI (isoforms α and β) are generated by alternative splicing. A significant proportion of TFPI molecules in blood are truncated to a variable extent at the COOH-terminal end, with resultant compromised inhibitory activity. The inhibitory activity of TFPI is enhanced by heparin. Upon heparin administration, TFPI is released from endothelial cells, with a 2- to 10-fold increase in circulating levels being achieved. Release of TFPI with heparin therapy is responsible for a portion of the observed elevation in PT and raises the possibility that part of the antithrombotic effect of heparin may be mediated by release of TFPI. A minor pool of TFPI (approximately 10% of the total TFPI in blood) is located within platelets.[185] Transgenic mice with complete TFPI deficiency do not survive.[186] There are no known human TFPI-deficient individuals.

TFPI is the principal stoichiometric inhibitor of the extrinsic pathway (see Figs. 27-2 and 27-4, *B*). The TFPI mechanism allows the factor VIIa–TF complex to initiate factor Xa formation, but it suppresses the generation of high levels of factor Xa product formation by binding the enzyme-product complex (see Fig. 27-4, *B*). The inhibitor mechanism involves rapid interaction between the second Kunitz domain of TFPI with the active site of factor Xa; localization of the complex to the membrane surface is mediated by the Gla domain of factor Xa.[49] Once surface bound, the factor Xa–TFPI complex rapidly inactivates TF–factor VIIa. This complex formation depends on binding of the first Kunitz domain of TFPI to the active site of factor VIIa. These interactions together form a stable quaternary complex, TF–factor VIIa–TFPI–factor Xa. The factor IXa–TFPI complex can also inhibit factor VIIa–TF, although the physiologic relevance of this route of inhibition is unclear because high plasma concentrations of TFPI are required. At normal plasma concentrations, this multicomponent interaction of TFPI allows basal function of the factor VIIa–TF complex but inhibits it after more extensive activation takes place.

When combined with the stoichiometric inhibitor AT, a synergistic regulatory effect of blood coagulation occurs by inducing kinetic “thresholds” such that the initiating TF stimulus must achieve a significant magnitude to propel thrombin generation.[187] TF concentrations below the threshold concentration are ineffective in promoting robust generation of thrombin because of the cooperative influence of the inhibitors; concentrations in excess of the threshold yield robust and almost equivalent thrombin generation. TFPI and the dynamic protein C–thrombomodulin-thrombin system also cooperate to provide threshold-limited, synergistic inhibition of thrombin production. In this instance, TFPI slows the initiation phase while the APC system reduces the availability of the cofactors factors Va and VIIIa, thereby shutting down the propagation phase of thrombin generation.

Antithrombin

AT is a member of the serpin proteinase inhibitor family and circulates in blood as a single-chain glycoprotein. Despite its name, AT inhibits not only thrombin but also most of the proteases in the coagulation pathway. Human AT circulates as two glycoforms, the α and β variants, which contain identical polypeptide backbones but differ in both carbohydrate content and heparin affinity. AT-β binds heparin more tightly than AT-α and is observed to preferentially accumulate on the vessel wall where heparan sulfate proteoglycans are exposed.[188]

AT has a broad spectrum of inhibitory activity, with most of its target proteases participating in the coagulation cascade. It is primarily an inhibitor of thrombin, factor Xa, factor IXa, factor VIIa–TF, factor XIa, factor XIIa, and plasma kallikrein[10,189] (see Fig. 27-2). AT also displays antiproliferative and antiinflammatory properties that may derive from its ability to inhibit thrombin. Heparin and heparan sulfate potentiate these reactions and are used in the treatment of thrombosis. When AT is complexed with heparin, its rate of binding to thrombin increases 1000-fold. The general mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure of the serpin to form a tight, equimolar (1 : 1) complex, followed by inactivating structural rearrangements of both AT and the protease.

Heparin Cofactor II (Leuserpin 2)

Heparin cofactor II is another member of the serpin family and is uniquely stimulated by the proteoglycan dermatan sulfate. The only coagulation enzyme inhibited by heparin cofactor II appears to be thrombin.[190] However, the rate of thrombin inhibition by heparin cofactor II in the absence or presence of glycosaminoglycans is significantly slower than inhibition by AT under similar conditions. In view of the fact that the plasma concentration of heparin cofactor II is 25% to 50% that of AT and that low levels of heparin cofactor II are not strongly associated with thrombosis, the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned.

Protein C Inhibitor (Plasminogen Activator Inhibitor 3)

Protein C inhibitor is a member of the serine proteinase inhibitor family. Its targets range from the procoagulant, anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen. Hereditary or acquired protein C inhibitor deficiency has not been documented. Protein C inhibitor–deficient mice show impaired spermatogenesis and male infertility.[191] The importance of the regulation of APC by protein C inhibitor in humans is suggested by the use of this complex as a marker for detection of deep vein thrombosis by immunofluorometric assay measurements.[192]

PROTEINS OF CLOT FORMATION

The central event in blood coagulation is the conversion of soluble fibrinogen (factor I) to insoluble cross-linked fibrin. This conversion is accomplished when thrombin removes small polar peptides (termed fibrinopeptides A and B) from the fibrinogen molecule forming fibrin. These fibrin molecules noncovalently interact with each other to form a fibrin web. Fibrin stabilization is accomplished by the action of a second coagulation enzyme (factor XIIIa) that introduces numerous covalent cross-links between these fibrin molecules. The resulting fibrin web is able to capture platelets and red blood cells, thus effectively sealing the wound and stemming plasma loss.

Factor XIII (Fibrin-Stabilizing Factor)

Factor XIII is a protransglutaminase that when proteolytically activated, can form cross-linked amide bonds between glutamyl and lysinyl residues. The zymogen circulates in plasma as a tetramer composed of two A and two B subunits. It plays an important role in hemostasis and thrombosis, as well as participates in the physiologic processes of cell proliferation and cell migration. The product enzyme factor XIII(a) has multiple substrates, including fibrin/fibrinogen, fibronectin, α_2-plasmin inhibitor, collagen, vitronectin, VWF, actin, myosin, factor V, and thrombospondin.[193-196]

Factor XIII is distributed into plasma and platelet pools. Plasma factor XIII circulates as a 320-kD A_2B_2 heterotetramer composed of two identical A chains and two B chains associated noncovalently.[197] The A subunit is the procatalyst and contains three important functional sites: the catalytic site, a calcium binding site, and the activation peptide.[198,199] The activation peptide of one A subunit limits access to the active site cysteine of the other A subunit of the dimer. The B chain has no enzymatic activity and has been thought to function as a carrier of the A subunit.[200]

Bone marrow is the prime site of synthesis of the A chain of plasma factor XIII,[201] which is also present intracellularly as a 160-kD A_2 homodimer in platelets, megakaryocytes, and monocytes.[202,203] How the A_2 dimer is transferred out of the cell and which cell types are the primary sources of plasma A_2 are not understood. Approximately 50% of the total potential factor XIII A chain activity in human blood is found in platelets.[202] The B subunit is synthesized in hepatocytes and secreted as a monomer.[204] After being secreted, the A and B subunits associate and become an A_2B_2 tetrameric molecule in plasma.

Plasma factor XIII is activated by cleavage of thrombin at the NH_2-terminal end of the A chains, with release of a 36–amino acid activation peptide. Catalytic activity is expressed only after the A chain dimer is dissociated from the B chain. Fibrin/fibrinogen plays an important role as a cofactor in dissociation of the B chains from thrombin-cleaved factor XIII.[201] The intracellular form of factor XIII contains only the A chain and thus does not require dissociation of the B chain.

Activation of factor XIII during blood clotting is tightly correlated with fibrin formation.[205] This creates a regulated system in which cross-linked polymers occur coincident with fibrin being formed. The rate of thrombin cleavage of plasma factor XIII has been shown to be greatly accelerated by the presence of fibrin polymers.[206] This positive feedback network between thrombin, fibrin/fibrinogen, and factor XIIIa ensures that a stable clot can form rapidly to maintain hemostasis. To date, no known endogenous inhibitor has been described that regulates this important enzyme.[193-196] Fibrin is the main physiologic substrate for factor XIIIa.

Fibrinogen (Factor I) and Fibrin

Fibrinogen is composed of six polypeptide chains (two $A\alpha$ chains, two $B\beta$ chains, and two γ chains); after

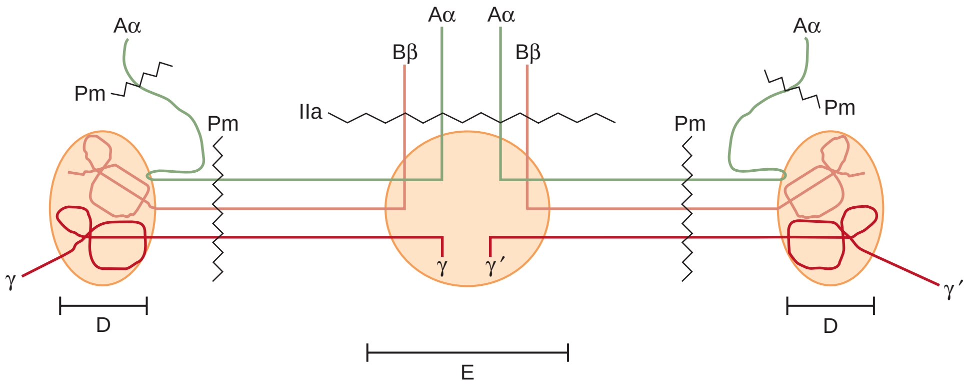

Figure 27-9 Schematic representation of fibrinogen to illustrate thrombin and plasmin cleavage sites in the intact molecule. The six polypeptide chains, Aα2Bβ2γ2 are folded into three globular structures, two "D" and one "E," which are connected by "coiled-coil" segments. The NH2-terminal regions of the Aα, Bβ chains extend from the central "E" domain and, when cleaved by thrombin, yield fibrinopeptide A and fibrinopeptide B. The macromolecular product fibrin is then referred to as $\alpha 2\beta 2\gamma 2$. A small fraction of fibrinogen contains a COOH-terminal extension of the γ chain that is referred to as γ′.

posttranslational modification, the mature protein circulates in blood with an average molecular weight of 340,000 (see Table 27-1).[207,208] The polypeptide chains are distributed into two symmetric half-molecules, each containing one Aα, one Bβ, and one γ chain, with the NH$_2$-terminal ends oriented toward each other (Fig. 27-9). The half-molecules are linked by noncovalent and disulfide bonds near their NH$_2$-terminal ends to yield a linear arrangement of three nodular structures. The outside two domains, formed by the COOH-terminal regions of the Bβ and γ chains of fibrinogen, are designated "D," whereas the central domain, which contains the NH$_2$-terminal ends of all the chains, is designated "E." Between 1.7 and 5 g of fibrinogen is synthesized per day by the liver, with approximately 75% of this fibrinogen being secreted into plasma and the remainder being distributed between the lymph and interstitial fluids.[209] Fibrinogen is an acute-phase reactant and is upregulated 2- to 10-fold in response to a variety of physiologic stresses, including trauma, pregnancy, and tissue inflammation.

The fibrinogen locus is composed of three closely linked genes (specifying the polypeptides Aα, Bβ, and γ) found as single copies in a region of approximately 50 kb. The three fibrinogen genes most likely evolved from a common ancestor through a series of duplications that began approximately 1 billion years ago.[210] Expression of the three chains is coordinately controlled and, at least for the hepatocyte, results in almost equal levels of mRNA for each chain in the cell.[211] Although most γ chains end at γ-Val411 (human numbering), approximately 10% of the time during splicing the last intron is retained, which results in a new chain, γ′, that ends at γ-Leu427.[212] A less common variant of the γ chain adds a 236–amino acid extension at the C-terminus.[213] After synthesis but before secretion, a number of posttranslational modifications occur, including glycosylation and phosphorylation. Factor XIIIa cross-linking occurs between sites on the Aα and γ chains but not on the Bβ chain.

Thrombin catalyzes the hydrolysis of Arg-Gly bonds, with small, polar NH$_2$-terminal pieces (fibrinopeptides) being removed from the α and β chains[207,208,214] (see Fig. 27-9). Cleavage of Aα-Arg16 by thrombin releases fibrinopeptide A (FPA) and forms fibrin I. The release of two FPA peptides exposes a site in the E domain that aligns with a complementary site in the D domain to form overlapping fibrils. Subsequent cleavage by thrombin at Bβ-Arg14 releases fibrinopeptide B (FPB) and leads to the formation of fibrin II, which presumably increases lateral aggregation of the protofibrils. FPA and FPB vary in length, between 13 and 21 amino acids in various mammals, and constitute less than 2% of the total mass.

Release of fibrinopeptides from fibrinogen results in the formation of an intermediate termed the fibrin monomer, which is all but indistinguishable from fibrinogen. In purified systems, removal of either FPA or FPB leads to formation of the fibrin dimer through noncovalent (i.e., charge-charge [salt links]) and hydrogen bond interactions. As fibrin monomers continue to be generated, the dimer elongates from both ends as a two-stranded molecule until it reaches approximately 30 monomers, at which point it becomes a protofibril. The second step in fibrin assembly is lateral association of the protofibrils into thicker fibrin fibers. These fibers are formed from the association of between 14 and 22 protofibrils. Because protofibrils, not dimers, are required for this step, it is believed that the forces involved in lateral association are weak and therefore become "strong" only in large numbers. Clots are known to branch, although how branching is accomplished is not clear.

The description of fibrinogen activation and fibrin assembly has been based on studies involving the use of citrated plasma or purified proteins, or both. To understand the in vivo process of fibrin formation, a system with nonanticoagulated blood has been used; in this experimental model the pattern of fibrin formation based on release of fibrinopeptide is different from systems using citrated plasma or purified fibrinogen.[205] In this study, most cleavage of FPA and subsequent clot formation take place just before the propagation phase of thrombin generation (Fig. 27-10). At the point of visual clot formation, virtually all fibrinogen (and some product

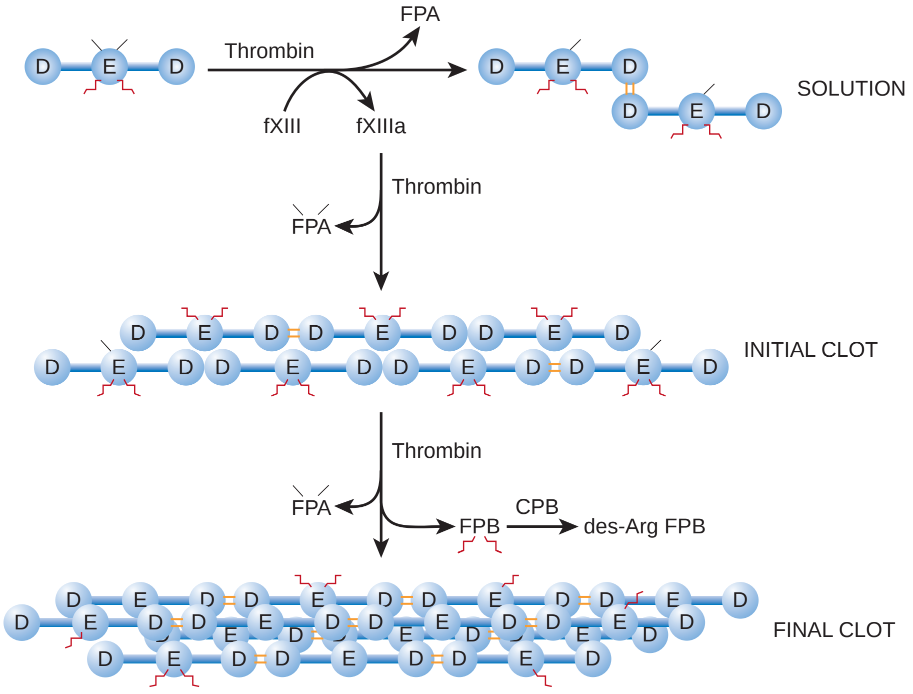

Figure 27-10 Schematic representation of whole blood fibrin formation. Thrombin at the beginning of clot formation simultaneously acts on fibrinogen (D-E-D) and factor XIII (fXIII). A portion (~40%) of fibrinopeptide A (FPA) is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent molecules. Activated factor XIII (fXIIIa) simultaneously cross-links adjacent D domains (D = D). Thus the initial soluble fibrin clot is composed of fibrinogen, fibrin, and γ-γ dimers with fibrinopeptide B (FPB) still attached. The initial clot is continuously acted on by thrombin, which releases the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The FPB released is selectively acted on by a carboxypeptidase B–like enzyme (CPB) to cleave the COOH-terminal arginine and produce des-Arg FPB. The significance of this cleavage is still unclear. *(Modified from Brummel KE, Butenas S, Mann KG: An integrated study of fibrinogen during blood coagulation.* J Biol Chem *1999;274: 22862-22870.)*

already cross-linked) disappears from the fluid phase of the reaction. Thus the "clot" appears to be a mixture composed of fibrin I and fibrinogen. The insoluble material present in the fibrin clot is virtually all cross-linked by factor XIIIa, whose activation occurs nearly simultaneously with removal of FPA[205] (see Fig. 27-10). It has been proposed that as many as six cross-links can form between a fibrin monomer and its neighbors and that the presence of these cross-links increases the strength, chemical resistance to urea, and lysis by plasmin.[207,208,215]

CONCLUSION

As the result of molecular investigation of blood coagulation for more than 100 years, the components of the blood coagulation system and their connections are well understood. Critical insights into this process and its regulation have often come from the study of patients with mutations in the genes encoding the relevant coagulation factors. It is only fitting that this knowledge has formed the basis for the development of reliable diagnostic tools and effective therapies for patients with both inherited and acquired disorders of hemostasis, as detailed in the ensuing chapters.

NON–PLASMIN-MEDIATED FIBRINOLYSIS

Fibrinolysis is the process by which the insoluble protein fibrin is converted to a defined set of soluble degradation products. It occurs in both intravascular and extravascular locations and is essential to human health and survival. Modern molecular biologic techniques have identified the major fibrinolytic genes, the mechanisms regulating their expression, and the consequences of their deficiency or overexpression in genetically engineered mice. In many cases these experiments have yielded surprising and instructive data that have revealed physiologic and pathophysiologic roles for the fibrinolytic system that are much more complex than originally thought. Furthermore, in the current genomic age, molecular analysis of human syndromes has identified specific mutations that result in either thrombosis secondary to fibrinolytic deficiency or hemorrhage secondary to fibrinolytic excess. In this chapter the molecular basis of fibrinolysis and its physiologic roles in human health and disease are reviewed.

BASIC CONCEPTS OF FIBRINOLYSIS

In response to vascular injury and activation of the coagulation cascade, thrombin induces polymerization of the soluble plasma protein fibrinogen, thereby producing an insoluble, cross-linked end product called fibrin (see Chapter 27). Once the flow of blood has been stemmed and vascular integrity restored, fibrin, which is found in both intravascular and extravascular sites, is cleared by a process known as fibrinolysis (Fig. 28-1, *A*). Normally, the fibrinolytic process is tightly regulated by a series of activators, inhibitors, cofactors, and receptors.[1] In the presence of fibrin, which serves as a cofactor for its own destruction, tissue plasminogen activator (tPA) is released from endothelial cells and possibly other cell types and interacts with the circulating zymogen plasminogen. Plasminogen, tPA, and fibrin form a ternary complex that accelerates the catalytic efficiency of plasmin generation by approximately 500-fold. Urokinase is also an efficient plasminogen activator (uPA), but its action is only minimally enhanced by fibrin. The action of plasmin on fibrin generates soluble fibrin degradation products, many of which have their own unique biologic properties.

The dynamic regulation of plasmin generation is complex. On the surface of a fibrin-containing thrombus, tPA and plasmin are protected from their major circulating inhibitors plasminogen activator inhibitor 1 (PAI-1) and α_2-antiplasmin (α_2-AP), respectively. On release into the circulation, however, plasmin and tPA are rapidly neutralized by these inhibitors and cleared by the liver. Because uPA and the nonenzymatic plasminogen activator streptokinase do not use fibrin as a cofactor, they function well in the fluid phase. Plasminogen may also be activated, albeit rather inefficiently, by proteases of the contact system such as kallikrein, factor XIa, and factor XIIa (see Chapter 27).

Cell surfaces represent protected environments in which plasmin can be generated without the risk of

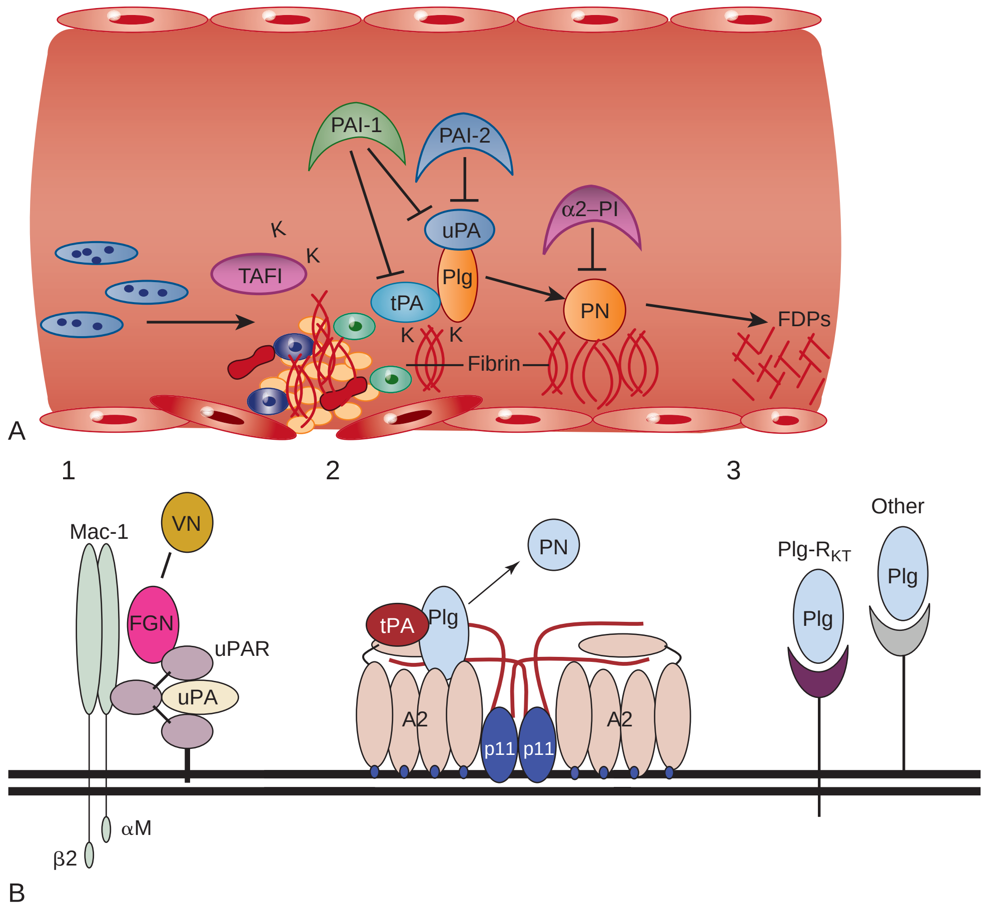

Figure 28-1 Overview of the fibrinolytic system. **A,** Fibrin-based plasminogen activation. The zymogen plasminogen (Plg) is converted to the active serine protease plasmin (PN) through the action of tissue plasminogen activator (tPA) or urokinase (uPA). The activity of tPA is greatly enhanced by its assembly with Plg through lysine residues (K) on a fibrin-containing thrombus. uPA acts independently of fibrin. Both tPA and uPA can be inhibited by plasminogen activator inhibitor 1 (PAI-1), which is released by endothelial cells, activated platelets, and other cells. PAI-2, on the other hand, neutralizes uPA more efficiently than it does tPA. By binding to fibrin, plasmin is protected from its major inhibitor α_2-antiplasmin (α_2-AP). Bound plasmin degrades cross-linked fibrin, which gives rise to soluble fibrin degradation products (FDPs). **B,** Some cell surface fibrinolytic receptors. *1,* Endothelial cells, monocytes, and macrophages express the uPA receptor (uPAR), which can interact with both uPA, thereby preserving its activity, and adhesive glycoproteins, such as fibrinogen (FGN) and vitronectin (VN). uPAR association with Mac-1 appears to facilitate adhesive interactions, whereas its interaction with uPA has a negative impact on adhesion. *2,* Endothelial cells, monocytes, and macrophages also express the annexin $(\text{A2-p11})_2$ complex, a coreceptor for tPA and Plg that augments the efficiency of plasmin generation. A2 forms a heterotetramer with protein p11, a member of the S100 family, which accentuates the efficiency of plasmin generation. *3,* Plasminogen receptors may be either transmembrane (Plg-R_{KT}) or peripheral membrane proteins (other). *(Modified from Ragno P: The urokinase receptor: a ligand or a receptor?* Cell Mol Life Sci *63:1028–1037, 2006.)*

neutralization by fluid-phase inhibitors (Fig. 28-1, *B*).[2] Endothelial cells, platelets, monocytes, macrophages, and some tumor cells all express protein receptor sites for plasminogen, tPA, or uPA.[3] The broad substrate specificity of plasmin observed in vitro may relate to its generation in nonvascular sites through fibrin-independent mechanisms. Plasmin may thus play an important role in extravascular events such as the modification of growth and differentiation factors, processing of matrix proteins, and activation of procoagulant molecules.

COMPONENTS OF THE FIBRINOLYTIC SYSTEM

Plasminogen

Synthesized primarily in the liver,[4,5] plasminogen is a single-chain proenzyme with a molecular weight (M_r) of approximately 92,000 that circulates in plasma at a concentration of approximately 1.5 μmol/L (Table 28-1).[6] The plasma half-life of plasminogen in humans is approximately 2 days.[7] Its 791 amino acids are cross-linked by 24 disulfide bridges, 16 of which yield five homologous triple-loop structures called *kringles*[8] (Fig. 28-2). The first (K1) and fourth (K4) of these 80–amino acid structures with an M_r of 10,000 impart high- and low-affinity lysine binding, respectively.[9] The lysine-binding domains of plasminogen appear to mediate its specific interactions with fibrin, cell surface receptors, and other proteins, including its circulating inhibitor α_2-AP.[10-14]

Posttranslational modification of plasminogen results in two glycosylation variants (forms 1 and 2)[15-17] (see Table 28-1). An *O*-linked oligosaccharide on Thr345 is common to both forms. Only form 2, however, contains an *N*-linked oligosaccharide on Asn288. The carbohydrate portion of plasminogen appears to regulate its

affinity for cellular receptors and may also specify its physiologic degradation pathway.

Activation of plasminogen results from cleavage of a single Arg-Val peptide bond at position 560 to 561,[18] which produces the active protease plasmin (see Table 28-1). Plasmin contains a typical serine protease catalytic triad[6] but exhibits broad substrate specificity in comparison to other proteases of this class.[19] The circulating form of plasminogen, amino-terminal glutamic acid plasminogen (Glu-Plg), is readily converted by limited proteolysis to several modified forms known collectively as lysine plasminogen (Lys-Plg).[20,21] Hydrolysis of the Lys77-Lys78

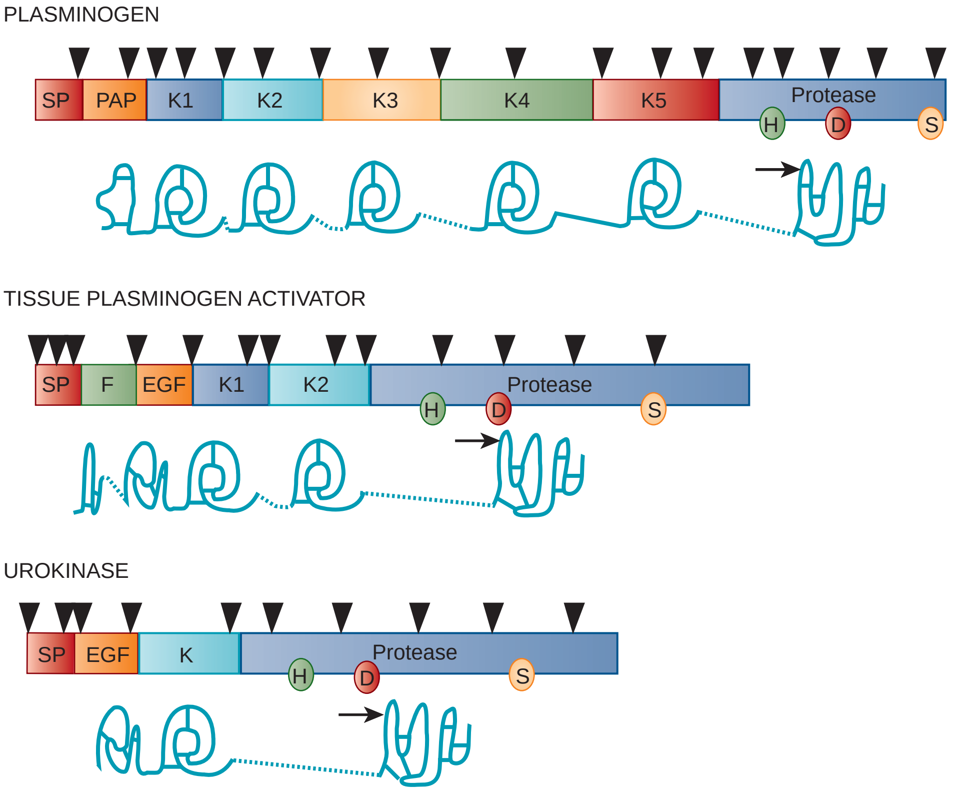

Figure 28-2 Structure-function relationships of plasminogen, tissue plasminogen activator (tPA), and urokinase (uPA) and alignment of the intron-exon structure of the plasminogen, tPA, and uPA genes with functional protein domains. Protein domains are labeled signal peptide (SP), preactivation peptide (PAP), kringle domains (K), fibronectin-like "finger" (F), epidermal growth factor–like domain (EGF), and protease. The approximate positions of the catalytic triad of amino acids histidine (H), aspartic acid (D), and serine (S) are shown within individual protease domains. The positions of individual introns relative to amino acid–encoding exons are indicated with *inverted triangles*.

peptide bond results in an altered conformation that more readily binds fibrin, displays twofold to threefold higher avidity for cellular receptors, and is activated 10 to 20 times more rapidly than Glu-Plg is.[12,18,22] Lys-Plg does not normally circulate in plasma[18] but has been identified on cell surfaces.[23]

Spanning 52.5 kilobases (kb) of DNA on chromosome 6q26-27, the plasminogen gene consists of 19 exons[24,25] and directs expression of a 2.7-kb messenger RNA (mRNA)[8] (see Fig. 28-2). Plasminogen gene activity is stimulated by the acute phase mediator interleukin-6, both in vitro and in vivo.[26] The gene is closely linked and structurally related to that of apolipoprotein(a), an apoprotein associated with the highly atherogenic low-density lipoprotein–like particle lipoprotein(a)[27] and more distantly related to other kringle-containing proteins such as tPA, uPA, hepatocyte growth factor, and macrophage-stimulating protein.[28-32] The significance of the latter two proteins to the fibrinolytic system remains to be determined.

Plasminogen Activators

Tissue Plasminogen Activator

One of the two major endogenous plasminogen activators, tPA, is a 527–amino acid glycoprotein with an M_r of approximately 72,000[33] (see Table 28-1). tPA contains five structural domains, including a fibronectin-like “finger,” an epidermal growth factor–like domain, two kringle structures homologous to those of plasminogen, and a serine protease domain (see Fig. 28-2). Cleavage of the Arg275-Ile276 peptide bond by plasmin converts tPA to a disulfide-linked, two-chain form.[33] Although single-chain tPA is less active than two-chain tPA in the fluid phase, both forms demonstrate equivalent activity when bound to fibrin.[34]

The two glycosylation forms of tPA are distinguishable by the presence (type 1) or absence (type 2) of a complex *N*-linked oligosaccharide moiety on Asn184 (see Table 28-1).[35,36] Both types, however, contain a high-mannose carbohydrate on Asn117, a complex oligosaccharide on Asn448, and an *O*-linked α-fucose residue on Thr61.[37] The carbohydrate moieties of tPA may modulate its functional activity, regulate its binding to cell surface receptors, and specify degradation pathways.

Located on chromosome 8p12-q11.2, the gene for human tPA is encoded by 14 exons spanning a total of 36.6 kb.[38-40] Most of the structural domains of tPA are encoded by one or two exons, and the organization of these exons is similar across related domains of tPA and the other fibrinolytic proteases (see Fig. 28-2). This observation suggests that the tPA gene arose by an evolutionary process called “exon shuffling,” whereby functionally related genes are generated through rearrangement of exons encoding autonomous domains. Consistent with this hypothesis, various functions of tPA can be localized to specific domains. For example, deletion of the fibronectin-like finger or kringle 2, but not kringle 1, results in a tPA resistant to the cofactor activity of fibrin, whereas catalytic activity in the absence of fibrin remains intact.[41]

The proximal promoter of the human tPA gene contains binding sequences for potentially important transcriptional factors, including AP1, NF1, SP1, and AP2,[42,43] as well as a potential cyclic adenosine monophosphate (cAMP)-responsive element.[44] In vitro, many agents have been shown to exert small effects on the expression of tPA mRNA, but relatively few enhance tPA synthesis without augmenting PAI-1 synthesis as well. Agents that regulate tPA gene expression independently of PAI-1 include arterial shear stress, thrombin, endotoxin, histamine, butyrate, retinoids, and dexamethasone.[45-50] Forskolin, which increases intracellular cAMP levels, has been reported to decrease the synthesis of both tPA and PAI-1.[43,51]

tPA is synthesized in the endothelial cell and stored within Rab3D-negative granules that are distinct from classical Weibel-Palade bodies.[52] Its release is governed by a variety of stimuli such as shear stress, butyrate, thrombin, histamine, bradykinin, epinephrine, acetylcholine, arginine vasopressin, gonadotropins, exercise, and venous occlusion.[45,47,53,54] Its circulating half-life is exceedingly short (≈5 minutes). By itself, tPA is a poor activator of plasminogen. However, in the presence of fibrin, the catalytic efficiency of tPA-dependent plasmin generation (k_{cat}/K_m) increases by at least 2 orders of magnitude[22] because of a dramatic increase in affinity (decreased Michaelis constant [K_m]) between tPA and its substrate plasminogen in the presence of fibrin. Although it is expressed by extravascular cells, tPA appears to represent the major intravascular activator of plasminogen.[19]

Urokinase

The second endogenous plasminogen activator, single-chain uPA or prourokinase, is a glycoprotein with an M_r of approximately 54,000 and consists of 411 amino acids (see Table 28-1). uPA contains an epidermal growth factor–like domain and a single plasminogen-like kringle and possesses a classic catalytic triad within its serine protease domain[55] (see Fig. 28-2). Cleavage of the Lys158-Ile159 peptide bond by plasmin or kallikrein converts single-chain uPA to a disulfide-linked two-chain derivative.[56] Located on chromosome 10, the human uPA gene is encoded by 11 exons spanning 6.4 kb and expressed by activated endothelial cells, macrophages, renal epithelial cells, and some tumor cells.[57,58] As noted earlier, its intron-exon structure is closely related to that of the tPA gene.

uPA may be induced during neoplastic transformation, possibly through a mechanism involving the transcription factors AP1 and AP2.[59] Other agents that appear to induce expression of uPA in vitro include hormones, growth factors, and cAMP.[49] Inflammatory cytokines such as interleukin-1 and lipopolysaccharide induce only small increments in uPA expression, whereas tumor necrosis factor and transforming growth factor β (TGF-β) have a more dramatic (5- to 30-fold) effect.[60-62]

Two-chain uPA occurs in both high-molecular-weight (M_r of 54,000) and low-molecular-weight (M_r of 33,000) forms that differ by the presence or absence, respectively, of a 135-residue amino-terminal fragment released by plasmin cleavage between Lys135 and Lys136.[63,64]

Although both forms are capable of activating plasminogen, only the high-molecular-weight form binds to the uPA receptor (uPAR). uPA has much lower affinity for fibrin than tPA does and is an effective plasminogen activator both in the presence and in the absence of fibrin.[65,66] The extent to which prourokinase possesses intrinsic plasminogen-activating capacity is an area of controversy.[67,68]

Accessory Plasminogen Activators

Under certain conditions, proteases traditionally classified within the intrinsic arm of the coagulation cascade (see Chapter 26) have been shown to be capable of activating plasminogen directly. Such proteases include kallikrein, factor XIa, and factor XIIa.[69-71] Normally, however, they account for no more than 15% of the total plasmin-generating activity in plasma.

Inhibitors of Fibrinolysis

Plasmin Inhibitors

The action of plasmin is negatively modulated by a family of ***ser***ine ***p***rotease ***in***hibitors called serpins[72] (see Table 28-1). All serpins share a common mechanism of action by forming an irreversible complex with the active-site serine of the target protease after proteolytic cleavage of the inhibitor by the target protease. Within such a complex, both protease and inhibitor lose their activity.

A single-chain glycoprotein with an M_r of approximately 70,000, α_2-AP circulates in plasma at relatively high concentrations (≈0.9 μmol/L) and has a plasma half-life of 2.4 days[73] (see Table 28-1). This serpin contains about 13% carbohydrate by mass and consists of 452 amino acids with two disulfide bridges.[74] In humans the gene is located on chromosome 18 and contains 10 exons distributed over 16 kb of DNA.[75] The promoter region of the α_2-AP gene contains a hepatitis B–like enhancer element that directs tissue-specific expression in the liver.[75] α_2-AP is also a constituent of platelet alpha granules.[76] Plasmin released into flowing blood or in the vicinity of a platelet-rich thrombus is immediately neutralized on forming an irreversible 1 : 1 stoichiometric, lysine binding site–dependent complex with α_2-AP. Interaction with plasmin is accompanied by cleavage of the Arg364-Met365 peptide bond, and the resulting covalent complexes are cleared in the liver.

Several other proteins inhibit the activity of fibrinolytic serine proteases (see Table 28-1). α_2-Macroglobulin (α_2-MG) is a tetrameric protein with an M_r of 725,000 that is synthesized by the liver, endothelial cells, macrophages, and fibroblasts and is found in platelet alpha granules. The gene for α_2-MG, which consists of 36 exons distributed over 48 kb of DNA on chromosome 12, directs the expression of a 1451–amino acid polypeptide.[77-79] As a generic inhibitor of all four classes of proteases (serine, cysteine, aspartyl, and metallo), α_2-MG is a nonserpin that inhibits plasmin with approximately 10% of the efficiency exhibited by α_2-AP by forming a noncovalent complex.[80] C1 esterase inhibitor can also serve as an inhibitor of tPA in plasma.[81] Protease nexin may function as a noncirculating cell surface inhibitor[82] of trypsin, thrombin, factor Xa, urokinase, or plasmin and result in protease-inhibitor complexes that are endocytosed via a specific nexin receptor.[83]

Thrombin-activatable fibrinolysis inhibitor (TAFI) is a plasma carboxypeptidase that acts as a potent inhibitor of fibrinolysis (see Table 28-1).[84] Identical to the previously cloned carboxypeptidase B[85] and the previously isolated carboxypeptidase U,[86] this single-chain polypeptide with an M_r of 45,000 circulates in plasma at concentrations of about 75 nmol/L and undergoes limited proteolysis in the presence of plasmin or thrombin, which leads to its activation.[87] Carboxypeptidase B–like molecules remove carboxyl-terminal lysine or arginine residues from fibrin and other proteins, thereby reducing binding of plasminogen to fibrin and cell surfaces and limiting plasmin generation.[88] The potentially antifibrinolytic effect of thrombin appears to be mediated through its ability to activate TAFI in the presence of thrombomodulin.[84,89] Anticoagulation by inhibition of factor XI also appears to have an antifibrinolytic effect in vivo by downregulation of thrombin-mediated activation of TAFI.[90] In a system of purified components, TAFI has been shown to reduce tPA-induced fibrinolysis half-maximally at approximately 1 nmol/L, which is well below its concentration in plasma.[91]

Plasminogen Activator Inhibitors

Plasminogen Activator Inhibitor 1. Of the two major plasminogen activator inhibitors[92] (see Table 28-1), PAI-1 is the most ubiquitous. This single-chain cysteine-less glycoprotein with an M_r of approximately 52,000 is released by endothelial cells, monocytes, macrophages, hepatocytes, adipocytes, and platelets.[93,94,95] Release of PAI-1 is stimulated by many cytokines, growth factors, and lipoproteins common to the global inflammatory response.[61,96-98] The PAI-1 gene consists of nine exons spanning 12.2 kb on chromosome 7q21.3-q22.[99] The serpin reactive site is located at Arg346-Met347, and activity of this labile serpin is stabilized upon complex formation with vitronectin, a component of plasma and the pericellular matrix.[100,101]

Regulation of PAI-1 gene expression is complex.[102-105] Agents that have been shown to enhance expression of PAI-1 at the message level, the protein level, or both without affecting the synthesis of tPA include the inflammatory cytokines lipopolysaccharide, interleukin-1, tumor necrosis factor α,[61,62,96,98,106-108] TGF-β and basic fibroblast growth factor,[60,96,103,105] very-low-density lipoprotein and lipoprotein(a),[109,110] angiotensin II,[111] thrombin,[107,112] and phorbol esters.[113] In addition, endothelial cell PAI-1 is downregulated by forskolin[51] and by endothelial cell growth factor in the presence of heparin.[114]

Plasminogen Activator Inhibitor 2. Originally purified from human placenta,[92,115] PAI-2 is a 393–amino acid member of the serpin family whose reactive site is the Arg358-Thr359 peptide bond[115] (see Table 28-1). The gene encoding PAI-2 is located on chromosome 18q21-23, spans 16.5 kb, and contains eight exons.[116] PAI-2 exists as both a nonglycosylated intracellular form with an M_r of 47,000 and a glycosylated form with an M_r of

60,000 secreted primarily by macrophages and keratinocytes. Functionally, PAI-2 inhibits both two-chain tPA and two-chain uPA with comparable efficiency (second-order rate constants of 10^5 mmol/L/sec). However, it is less effective in inhibiting single-chain tPA (second-order rate constant of 10^3 mol/L/sec) and does not inhibit prourokinase.

Significant levels of PAI-2 are found in human plasma only during pregnancy but can be markedly enhanced in vitro by the inflammatory mediator tumor necrosis factor.[117] Regulation of PAI-2 gene expression is modulated by a variety of factors, including a number of inflammatory mediators.[118-121] In macrophages in vitro, secretion of PAI-2 is enhanced by endotoxin and phorbol esters.[121,122]

Cellular Receptors in Fibrinolysis

Though structurally diverse, cell surface fibrinolytic receptors can be classified into two groups whose integrated actions are likely to be essential for homeostatic control of plasmin activity[3] (see Table 28-1). Activation receptors localize and potentiate plasminogen activation, whereas clearance receptors eliminate plasmin and plasminogen activators from the blood or focal microenvironments.

Activation Receptors

Plasminogen Receptors. Plasminogen receptors are a diverse group of proteins expressed on a wide array of cell types.[3] Receptors reported include α-enolase, glycoprotein IIb-IIIa complex, the Heymann nephritis antigen, amphoterin, and the annexin A2 (A2) complex (A2-p11) (see Table 28-1) and have been found to be expressed primarily on monocytoid cells,[123,124] platelets,[125] renal epithelial cells,[126] neuroblastoma cells,[127] and endothelial cells,[128-130] respectively. In addition, Plg-R_{KT}, expressed mainly on macrophages, is the first transmembrane plasminogen receptor to be identified, and it appears also to bind tPA (see Table 28-1).[131,132] All plasminogen receptors appear to interact with the kringle structures of plasminogen through carboxyl-terminal lysine residues.

The Urokinase Receptor. uPAR is expressed on monocytes, macrophages, fibroblasts, endothelial cells, and a variety of tumor cells[3] (see Table 28-1). uPAR complementary DNA (cDNA) was cloned and sequenced from a human fibroblast cDNA library[133] and encodes a protein of 313 amino acids with a 21-residue signal peptide. The gene structure consists of seven exons distributed over 23 kb of genomic DNA, which places this glycoprotein within the Ly-1/elapid venom toxin superfamily of cysteine-rich proteins.[134-136] uPAR is anchored to the plasma membrane through glycosylphosphatidylinositol linkages.[137] uPA bound to its receptor maintains its activity and susceptibility to PAI-1.[138] Formation of uPA–PAI-1 complexes appears to hasten clearance of uPA by hepatic or monocytoid cells.[139-141]

High-resolution (1.9 to 2.7 Å) analysis of the crystal structure of a complex formed by various amino-terminal uPA peptides and a soluble form of uPAR reveals that uPA engages a central cone-shaped cavity in uPAR formed by its three-finger motif. This arrangement leaves surface residues of uPAR available for binding of other proteins, such as integrins and vitronectin. It is therefore postulated that these interactions may be regulated by binding of uPA itself.[142-144]

Aside from a potential role in fibrinolysis, uPAR appears to play a pivotal role in cellular signaling and adhesion events.[145] uPAR binds to the adhesive glycoprotein vitronectin at a site distinct from the uPA-binding domain,[146,147] and uPAR-transfected renal epithelial cells acquire enhanced adhesion to vitronectin and lose their adhesion to fibronectin.[148] Furthermore, uPAR colocalizes with integrins in focal contacts and at the leading edge of migrating cells[149] and also associates with caveolin, a major component of caveolae, structures abundant in endothelial cells and thought to participate in signaling events.[150-152] Thus integrin function may be regulated by uPAR, an association signifying an integrated relationship between cellular adhesion and proteolysis.

These findings have important implications for the behavior of malignant cells, in which uPAR is frequently overexpressed.[152] High-level uPAR expression also appears to be an indicator of a poor prognosis in breast, lung, colon, esophageal, and gastric cancer.[153] uPA has been identified by protease activity profiling as being important in intravasation of fibrosarcoma,[154] and RNA interference–mediated "knockdown" of uPA and uPAR seems to block the in vivo invasiveness of highly malignant cells.[154,155]

The Annexin A2 Complex. Annexin A2 (A2) is a widely distributed, highly conserved, peripheral membrane protein with an M_r of 36,000 that is expressed abundantly on endothelial cells,[128-130] monocyte/macrophages,[159,160] myeloid cells,[161] and some tumor cells[162-164] (see Table 28-1). It belongs to a more than 60-member superfamily of calcium-dependent, phospholipid-binding proteins[165,166] that have in common a conserved carboxyl-terminal "core" region preceded by a more variable amino-terminal "tail."[167] The human *ANXA2* gene consists of 13 exons distributed over 40 kb of genomic DNA on chromosome 15 (15q21).[168]

At membrane surfaces, A2 forms a heterotetrameric complex with S100A10 (p11) [$(A2\text{-}p11)_2$]. A2 possesses the unique property of binding both plasminogen (K_d of 114 nmol/L)[129] and tPA (K_d of 30 nmol/L),[169] but not uPA,[128,170] and purified native human A2 stimulates the catalytic efficiency of tPA-dependent plasminogen activation by sixtyfold.[171] This effect is completely inhibited in the presence of lysine analogues or on treatment of A2 with carboxypeptidase B, an agent that removes basic carboxyl-terminal amino acids. Although it lacks a classic signal peptide, A2 is constitutively translocated to the endothelial cell surface within 16 hours of its biosynthesis, where it binds phospholipid via core repeat 2.[172] The $(A2\text{-}p11)_2$ complex may stimulate tPA-dependent plasmin generation even more strongly.[173]

Expression of the A2 complex on the endothelial cell surface appears to be highly regulated.[170] Translocation of A2 to the cell surface requires association with p11, tyrosine phosphorylation of A2 at tyrosine 23 by an src-like kinase, and an activating stimulus such as heat stress or thrombin stimulation.[174,175] Intracellular concentrations of p11 are regulated by A2, which masks a polyubiquitination site on p11; in the absence of sufficient A2, uncomplexed p11 is rapidly ubiquitinated and directed to the proteasome for degradation.[176] In a negative-feedback mechanism, furthermore, plasmin formed on the endothelial cell surface induces activation of PKC, which phosphorylated serines 11 and 23 on A2, dissociates the $(A2\text{-}p11)_2$ tetramer and reduces further translocation.[177]

Lipoprotein(a), an atherogenic low-density lipoprotein–like particle, competes with plasminogen for binding to A2[178,179] and reduces cell surface plasmin generation. Lipoprotein(a) contains an apoprotein called apoprotein(a) that contains kringle structures highly homologous to those of plasminogen.[27] This mechanism may contribute to atherogenesis by reducing fibrinolytic surveillance at the blood vessel wall.

Binding of tPA to A2 requires residues 8 to 13 (LCKLSL) within the amino-terminal "tail" domain of the receptor.[180] This sequence is a target for homocysteine (HC), a thiol-containing amino acid that accumulates in association with nutritional deficiencies of vitamin B_6, vitamin B_{12}, or folic acid or in inherited abnormalities of cystathionine β-synthase, methylenetetrahydrofolate reductase, or methionine synthase; it is associated with atherothrombotic disease.[181-183] In vitro, HC impairs the intrinsic fibrinolytic system of the endothelial cell by approximately 50%[184] by forming a covalent derivative with Cys9 of A2, thereby preventing its interaction with tPA.[184] The half-maximal dose of HC for inhibition of binding of tPA to A2 is approximately 11 μmol/L HC, a value close to the upper limit of normal for HC in plasma (14 μmol/L).

Studies in homozygous A2-null mice have revealed that A2 contributes to intravascular fibrin balance in vivo[185] (Table 28-2). A2 knockouts display microvascular fibrin deposition, reduced clearance of arterial thrombi, and markedly deficient microvascular endothelial cell surface plasmin generation.[186] In addition, pretreatment of the rat carotid artery with A2 prevents vessel thrombosis in response to injury.[187] A2-null mice also display defects in angiogenesis reflected in several systems, including oxygen-induced retinopathy, a model of retinopathy of prematurity, in which prevention of fibrin formation relieved the block to new blood vessel formation.[186,188] In mice with diet-induced hyperhomocysteinemia, moreover, fibrin accumulation and impaired angiogenesis were reversed on infusion of fresh, unmodified A2.[189]

In humans, moreover, overexpression of A2 has been associated with hemorrhagic disease.[190] Overexpression of A2 by acute promyelocytic leukemia (APL) cells correlates with the initial severity of hemostatic compromise at the time of diagnosis.[161,191,192] Elevated expression of p11 has also been demonstrated in an APL cell line that harbors the [t(15;17)(q22-24;q12-21)] translocation characteristic of APL.[193] It is interesting to note that diet-induced hyperhomocysteinemia has been demonstrated to reverse the hyperfibrinolytic coagulopathy in a murine model of APL.[194]

Conversely, A2 system dysfunction appears to correlate with vascular occlusive disease.[190] Patients with antiphospholipid syndrome and anti-A2 antibodies have a significantly higher risk for clinical thrombosis than do patients who lack this antibody.[195] Similarly, high titer auto-antibodies to A2 are associated with thrombosis and maternal-fetal complications in pregnancy[196] and were unusually prevalent in a cohort of patients with cerebral thrombosis.[197] In sickle cell disease, moreover, A2 polymorphisms are associated with vaso-occlusive stroke, osteonecrosis of bone, and possibly pulmonary hypertension.[198-201]

Clearance Receptors

Both uPA and tPA are cleared from the circulation via the liver.[202] In vitro, clearance of tPA–PAI-1 complexes also appears to be mediated by a large two-chain receptor called the low-density lipoprotein receptor–related protein (LRP).[202-205] This complex interaction requires both the growth factor and finger domains of tPA. An additional "receptor-associated protein" with an M_r of 39,000 copurifies with LRP and may regulate the binding and uptake of LRP ligands.[206] LRP-knockout embryos undergo developmental arrest by 13.5 days after conception, which suggests that regulation of serine protease activity may be crucial for early embryogenesis.[207,208] Although several PAI-1–independent clearance pathways for tPA involving the large LRP subunit,[209] the mannose receptor,[210] or an α-fucose–specific receptor[211] have been proposed, in vivo studies in mice suggest that LRP and the mannose receptor play a dominant role in clearance of tPA.[212]

THE FIBRINOLYTIC ACTIONS OF PLASMIN

Fibrinogen

Fibrinogen possesses distinct proteolytic cleavage sites for plasmin and thrombin (Fig. 28-3). Whereas plasmin cleaves carboxyl-terminal Aα and amino-terminal fibrinopeptide B moieties, thrombin primarily releases fibrinopeptide A, which exposes the Gly-Pro-Arg tripeptide sequence and allows fibrinogen to polymerize and form insoluble fibrin[213] (see Chapter 27). Cleavage of fibrinogen (M_r of 340,000) by plasmin initially produces carboxyl-terminal fragments from the α chain within the D domain of fibrinogen (Aα fragment).[214-217] Simultaneously, but more slowly, the amino-terminal segments of the β chains are cleaved, with release of a peptide containing fibrinopeptide B. The resulting molecule with an M_r of approximately 250,000 is termed fragment X and represents a clottable form of fibrinogen. Additional cleavage events may release the Bβ fragment from the carboxyl-terminal of the β chain, and in a series of subsequent reactions, plasmin cleaves the three polypeptide chains that connect the D and E domains to produce a free D domain (M_r of ≈100,000) plus the binodular D-E fragment known as fragment Y (M_r of ≈150,000). Finally, domains D and E are separated from each other, and some of the amino-terminal fibrinopeptide A sites on domain E are also modified. Although fragment X can be converted to fibrin by thrombin, the fragments Y, D, and

α_2AP, α_2-Antiplasmin; *A2*, annexin 2; *FgnA*, fibrinogen A; *nl*, normal; *PAI-1*, plasminogen activator inhibitor-1; *PAI-2*, plasminogen activator inhibitor-2; *PLG*, plasminogen; *TAFI*, thrombin-activatable fibrinolysis inhibitor; *uPA*, urokinase; *uPAR*, urokinase receptor.

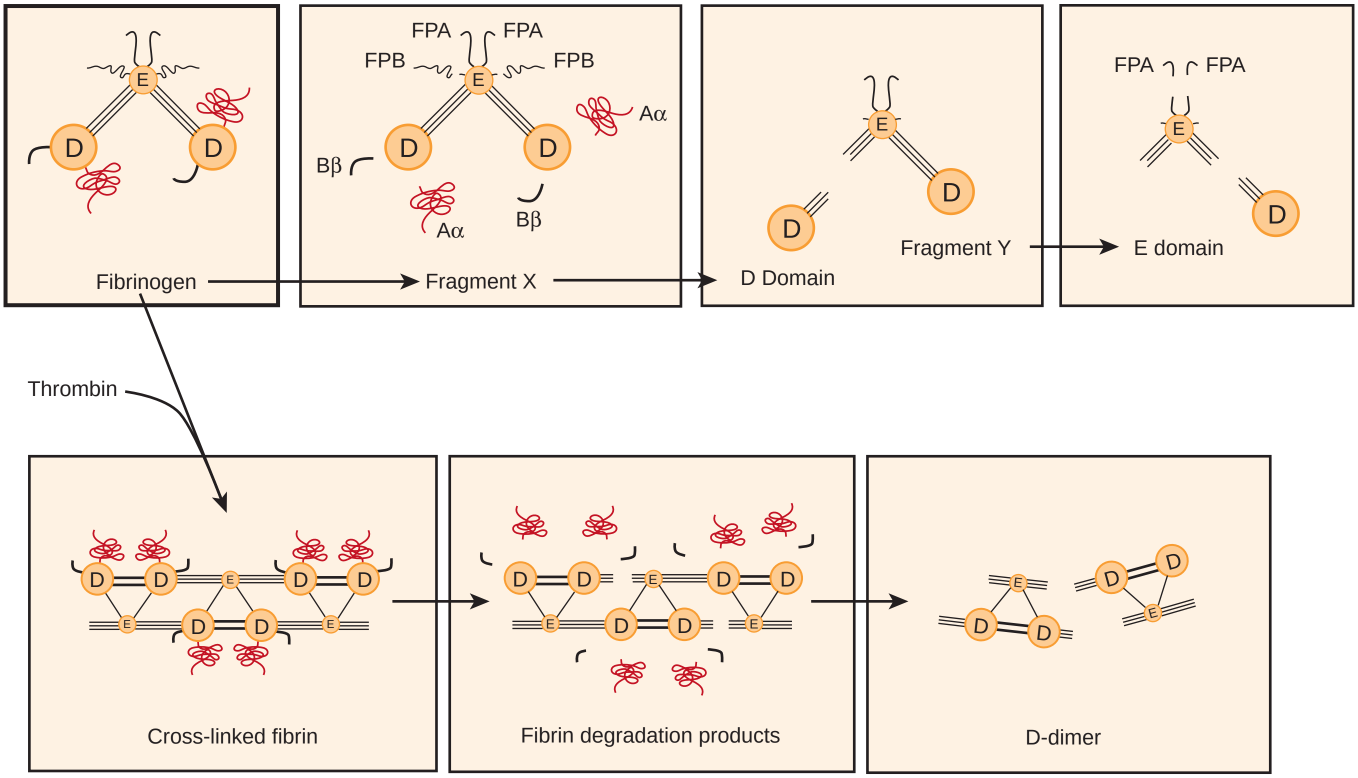

Figure 28-3 Degradation of fibrinogen and cross-linked fibrin by plasmin. *Top panel,* Plasmin initially cleaves the carboxyl-terminal regions of the α and β chains within the D domain of fibrinogen, thereby releasing the Aα and Bβ fragments. In addition, a fragment containing fibrinopeptide B (FPB) from the amino-terminal region of the β chain is released, forming the intermediate product known as fragment X. Fibrinopeptide A (FPA) remains intact. Subsequently, plasmin cleaves the three polypeptide chains connecting the D and E domains, which produces fragments D, E, and Y, and releases FPA. *Bottom panel,* Fibrinogen can also be polymerized by thrombin to form fibrin. When degrading cross-linked fibrin, plasmin initially cleaves the carboxyl-terminal region of the α and β chains within the D domain. Subsequently, some of the connecting regions between the D and E domains are severed. Fibrin is ultimately solubilized upon hydrolysis of additional peptide bonds within the central portions of the coiled-coil connectors, giving rise to fibrin degradation products such as D-dimer.

E are all nonclottable and may in fact inhibit the spontaneous polymerization of fibrinogen.[218]

Fibrin

Degradation of fibrin by plasmin leads to a distinct set of molecular products.[218] Species similar to fragments Y, D, and E but lacking fibrinopeptide sites are released from non–cross-linked fibrin. If fibrin has been extensively cross-linked by factor XIII, however, the resulting D fragments are cross-linked to an E domain fragment. An assay of cross-linked D-dimer fragments is used clinically to identify disseminated intravascular coagulation–like states associated with excessive plasmin-mediated fibrinolysis. Several biologic activities, including inhibition of platelet function,[219,220] potentiation of the hypotensive effects of bradykinin,[220] chemotaxis,[221] and immune modulation, have been ascribed to fibrin breakdown products.[222]

Tissue Plasminogen Activator–Mediated Plasminogen Activation

With or without fibrin, tPA-mediated activation of plasminogen follows Michaelis-Menten kinetics.[22] In the absence of fibrin, tPA is a weak activator of plasminogen. However, in the presence of fibrin, the catalytic efficiency (k_{cat}/K_m) of tPA-dependent plasminogen activation is enhanced by at least 2 orders of magnitude. This is the basis for its specificity as a lytic agent in the treatment of thrombosis. The affinity between tPA and plasminogen in the absence of fibrin is low (K_m of 65 μmol/L) but increases about 400-fold in its presence (K_m of 0.16 μmol/L), even though the catalytic rate constant remains essentially unchanged (k_{cat} of ≈0.05 sec^{-1}). When plasmin forms on the fibrin surface, both its lysine binding sites and its active site are occupied. Thus it is relatively protected from its physiologic inhibitor α_2-AP.[223] The interaction of tPA with fibrin is probably initiated by its finger domain. However, once fibrin is modified by plasmin, carboxyl-terminal lysine residues are generated, and these residues become binding sites for kringle 2 of tPA and kringles 1 and 4 of plasminogen.[224] Therefore fibrin accelerates its own destruction by (1) enhancing the catalytic efficiency of plasmin formation by tPA, (2) protecting plasmin from its physiologic inhibitor α_2-AP, and (3) providing new binding sites for plasminogen and tPA once its degradation has begun.

Urokinase-Mediated Plasmin Generation

For activation of Glu-Plg by uPA in a fibrin-free system, reported K_m values vary from 1.4 to 200 μmol/L, whereas

k_{cat} values range from 0.26 to 1.48 sec^{-1}. Interestingly, activation of Glu-Plg by two-chain uPA is minimally increased in the presence of fibrin, and uPA does not bind to fibrin.[225] In contrast, single-chain uPA has considerable fibrin specificity. This may reflect neutralization by fibrin of components in plasma that impair plasminogen activation.[226] It may also reflect a conformational change in plasminogen on binding to fibrin.[227] It is important to recognize, however, that the intrinsic plasminogen-activating potential of single-chain uPA is less than 1% that of two-chain uPA. Two-chain uPA has been used effectively as a thrombolytic agent for many years.[228]

PHYSIOLOGIC FUNCTIONS OF THE FIBRINOLYTIC SYSTEM

Thrombosis and Thrombolysis

Congenital plasminogen deficiency was first reported in a 31-year-old man with recurrent thrombosis.[229] In groups of patients with plasminogen deficiency, however, whether type I, in which both immunologically detectable protein and enzymatic function are decreased, or type II, in which just plasminogen function is impaired, only about 25% of patients report a history of thrombosis.[230-232] Indeed, the most common clinical manifestations of plasminogen deficiency, occurring in 80% and 34% of patients, respectively, are ligneous conjunctivitis and ligneous gingivitis, disorders characterized by the deposition of fibrin-rich pseudomembranes on mucosal surfaces.[233] These findings strongly suggest that plasminogen acts in extravascular as well as intravascular locations.[234-236]

The relative infrequency of thrombosis in patients with plasminogen deficiency may, in part, reflect the fact that in only a small fraction of patients with sonographic evidence of thrombosis does symptomatic vascular occlusion eventually develop.[237] In a study of consecutive patients with thrombophilia, the prevalence of plasminogen deficiency was only 1.9%.[238] Similarly, congenital deficiencies of plasminogen activators (tPA and uPA) have not been linked to thrombophilia in humans.[239] On the other hand, increased levels of PAI-1 were prevalent in young survivors of myocardial infarction.[240] Additionally, TAFI levels above the 90th percentile in a case-control study approximately doubled the risk for venous thrombosis.[241-243] Together these data suggest that measurement of plasma plasminogen or its activators in patients with thrombophilia is likely to be a low-yield procedure, whereas assessment of global fibrinolytic function using a phospholipid-based assay may be of value.

As one might expect, congenital deficiency of either α_2-AP or PAI-1 is generally associated with delayed rebleeding at sites of trauma or wound healing.[244,245] In patients with the Quebec platelet disorder, tandem duplication of the urokinase gene with overproduction of this plasminogen activator generally leads to a bleeding diathesis.[246] To date, no human disorders reflecting primary deficiencies of fibrinolytic receptors have been reported.

In general, analyses of genetically engineered mice support the hypothesis that the fibrinolytic system functions to regulate fibrin balance in both the intravascular and extravascular compartments (see Table 28-2). That fibrinogen is central to hemostasis is underscored by findings of postnatal bleeding at multiple sites in fibrinogen-null mice,[247] similar to that seen in human patients with afibrinogenemia. Similarly, although mice deficient in plasminogen have normal embryogenesis, survive to adulthood, and can sire offspring, they display significant runting, spontaneous thrombi develop in multiple tissues, and extravascular fibrin accumulates in the liver (see Table 28-2).[248,249] Ulcerative lesions are observed in the gastrointestinal tract, particularly the rectum, where prolapse is also seen. Plg$^{-/-}$ mice also clear induced thrombi much less readily than wild-type mice do,[250] and this defect is reversed by bolus injection of exogenous plasminogen.[251] Because the spontaneous thrombosis observed in plasminogen-deficient mice is completely reversed when fibrinogen is also deleted, it is clear that the thrombosis observed in plasminogen deficiency is related to failure of intravascular fibrin clearance.[252] Some strains of Plg-deficient mice also display ligneous conjunctivitis, a disorder similar to that observed in humans with plasminogen deficiency.[253]

Because no examples of complete deficiency of tPA or uPA have been documented in humans, the most compelling evidence for their role in fibrin balance derives from gene-knockout experiments in the mouse (see Table 28-2).[254] Both uPA- and tPA-null mice exhibit normal fertility and embryonic development. Although little spontaneous thrombosis is seen in either genotype, uPA$^{-/-}$ mice exhibit occasional fibrin deposition and tPA-deficient mice display impaired lysis of artificially induced pulmonary thrombi. In contrast, doubly deficient (tPA$^{-/-}$, uPA$^{-/-}$) mice exhibit extensive spontaneous fibrin accumulation in multiple organs, rectal prolapse, runting, and cachexia, all reminiscent of the phenotype seen in Plg$^{-/-}$ mice. These findings demonstrate that tPA and uPA are not essential for normal embryologic development, but they do play crucial roles in the activation of plasminogen, in the lysis of spontaneous and induced thrombi, and in fibrinolytic surveillance.

Although complete PAI-1 deficiency in humans is associated with a moderately severe bleeding tendency, mice deficient in PAI-1 exhibit normal development, survival, and fertility, with no evidence of spontaneous hemorrhage[255] (see Table 28-2). PAI-1–deficient mice do, however, exhibit resistance to thrombosis after injury[256] and enhanced sensitivity to thrombolytic therapy.[257] On the other hand, in transgenic mice that overexpress human PAI-1, a dramatic vascular occlusive process develops in the tail and hind limbs.[258] This finding may be attributable to unique effects of human PAI-1 in the mouse because mice overexpressing murine PAI-1 do not exhibit this abnormality.[259]

Deficiency of α_2-AP, the major serpin directly blocking plasmin activity, is a rare cause of bleeding disorder in humans.[260] Although no overt bleeding is seen in α_2-AP–deficient mice, increased lysis of artificially induced thrombi has been reported.[261] PAI-2–deficient mice exhibit no obvious phenotype even when PAI-1 is also absent in doubly deficient animals.[262] Complete TAFI deficiency in mice is fully compatible with life and does not appear to alter the response to vascular injury, artificially induced thrombosis, or endotoxin-induced disseminated intravascular coagulation.[263]

Mice transgenic for the catalytically inactive plasminogen analogue apolipoprotein(a) are subject to atherosclerosis and resistant to tPA-induced lysis of experimental pulmonary emboli.[264] The accelerated atherosclerosis observed in these mice is blunted under conditions of concomitant fibrinogen deficiency.[265] These data suggest that apolipoprotein(a)-associated atherosclerosis may be rooted in functional plasminogen deficiency and accumulation of intravascular fibrin. In addition, meta-analysis indicates a clear association between elevated plasma levels of Lp(a) and the occurrence of venous thromboembolism.[266]

Whereas complete deficiency of uPAR is associated with normal lysis of intravenously injected plasma clots in mice,[267] A2-deficient mice have impaired lysis of experimentally induced thrombi, and fibrin accumulates in both intravascular and extravascular locations.[186] In addition, A2-deficient microvascular endothelial cells lack tPA cofactor activity and migrate slowly through fibrin and collagen matrices. Interestingly, infusion of recombinant A2 amplifies the thrombolytic efficacy of tPA in a rat model of thromboembolic stroke, potentially reducing the hemorrhagic consequences of tPA-based stroke therapy.[268]

Wound Healing and Tissue Fibrosis

As discussed earlier, extravascular fibrin deposition is a hallmark of plasminogen deficiency in both mice and humans.[269,270] Plasminogen-deficient mice, as well as uPA$^{-/-}$/tPA$^{-/-}$ but not uPAR$^{-/-}$/tPA$^{-/-}$ mice, also exhibit defective wound healing characterized by impaired keratinocyte migration despite abundant neovascularization and granulation tissue within experimental wounds. Although fibrinogen-deficient mice exhibit subtle histologic defects in wound repair, the impaired healing in plasminogen-deficient mice disappears when fibrinogen is also absent.[271] Consistent with the hypothesis that plasmin is necessary for clearance of extravascular fibrin, deficiency of either PAI-1 or α_2-AP in mice is associated with accelerated cutaneous wound healing.[272,273] In addition, sciatic nerve regeneration after crush injury also appears to require tPA/plasmin-mediated clearance of fibrin to protect against axonal degeneration and demyelination.[274] Surprisingly, TAFI deficiency seems to be associated with impaired, rather than accelerated, healing of cutaneous wounds.[275]

Although extravascular fibrin commonly forms in response to injury, its exact role in tissue fibrosis is unclear. In a well-established model of bleomycin-induced pulmonary fibrosis, plasminogen$^{-/-}$, tPA$^{-/-}$, and uPA$^{-/-}$ mice, but neither uPAR$^{-/-}$ nor fibrinogen$^{-/-}$ mice, have increased deposition of both fibrin and collagen after injury.[276-278] Similarly, PAI-1–deficient mice, exhibit less bleomycin-induced pulmonary fibrosis than wild-type animals do.[278] Surprisingly, however, fibrin does not seem to be a prerequisite for the induction of pulmonary fibrosis in this model because mice deficient in fibrinogen were susceptible to fibrosis to the same degree as wild-type animals.[279] Thus the mechanism by which fibrinolytic proteins regulate fibrosis may relate to modulation of adhesive interactions that promote leukocyte adherence rather than plasmin catalytic activity.

Atherosclerosis and Cardiovascular Remodeling

Atherosclerosis is thought to represent a response to vascular injury that leads to atheromatous plaque formation and vascular remodeling.[280] In the setting of apolipoprotein E deficiency, simultaneous plasminogen deficiency accelerates vessel wall disease.[281] In this model fibrin is not strictly required for the development of atherosclerotic lesions, thus suggesting that the role of plasmin may relate to its ability to remove one or more nonfibrin substrates, liberate one or more growth factors from extracellular matrix, or activate crucial proteases.[282] Interestingly, although plasminogen deficiency accelerates hyperlipidemic atherosclerosis, the same mice are relatively resistant to transplant-associated atherosclerosis.[283]

Plasmin appears to promote the pathologic response to vascular and myocardial injury.[284] After induction of myocardial infarction in plasminogen-null mice, myocardial healing was markedly inhibited inasmuch as inflammatory cells failed to appear at the wound site, necrotic cardiomyocytes failed to disappear, and granulation and fibrous tissue failed to develop.[285] Similarly, healing of electrically injured femoral arteries, arteries treated with a flexible cuff, or arteries undergoing guidewire endothelial denudation was impaired in plasminogen-null mice, with reduced infiltration of inflammatory and smooth muscle cells and decreased neointima formation.[250,286,287] All these processes require cellular migration, which may entail plasmin-dependent matrix remodeling through activation of downstream matrix metalloproteinase 1 (MMP-1) and matrix metalloproteinase 3 (MMP-3).[288-290]

Plasmin may play a role in the activation of growth factors and in the proliferative response to blood vessel injury. Macrophages cultured on labeled matrices release both basic fibroblast growth factor and TGF-β into the medium in a plasminogen-dependent fashion.[291] TGF-β, a homodimeric polypeptide with an M_r of 25,000 whose effects on vascular cell growth and differentiation are pleiomorphic,[292] also appears to be converted from a latent to an active form by cell-associated plasmin. The latter process can be blocked by the presence of plasmin inhibitors such as aprotinin or α_2-AP and appears to involve alteration of its tertiary structure on cleavage of an amino-terminal glycopeptide.[293]

uPA but neither tPA nor uPAR appears to be required for vascular cell migration and pericellular plasmin formation in some injured vessels.[294,295] uPA appears to mediate the activation of MMPs in both atherosclerotic aortic aneurysm[296] and postinfarction cardiac rupture,[297] presumably through its activation of plasmin rather than direct cleavage of pro-MMPs. Together, these data suggest a unique role for uPA in postinjury vascular remodeling.

Tumor Biology

Tumor cells may use the fibrinolytic system for local invasion and metastasis. Although plasminogen-deficient mice display normal growth of both primary and metastatic tumors in the Lewis lung carcinoma model,[298] pulmonary metastases from a polyoma middle T antigen–induced mammary cancer were significantly reduced in plasminogen-null animals.[299] Fibrinogen-null mice exhibited normal growth of implanted Lewis lung carcinoma, whereas lymph node and hematogenous lung metastases were markedly reduced in both Lewis lung carcinoma and melanoma.[300,301] On the other hand, p11-null mice seem to exhibit reduced growth of implanted Lewis lung carcinoma in association with impaired recruitment of macrophages.[302] These data suggest that plasmin-mediated fibrin clearance may be required for tumor cell invasion, recruitment of tumor-supporting cells, or metastasis in some specific settings.

Analysis of tumor behavior in mice with genetic alterations in other components of the fibrinolytic system has produced a spectrum of results. uPA-deficient mice displayed markedly diminished murine sarcoma cell proliferation and tumor-associated angiogenesis when compared with wild-type animals.[303] These mice also failed to support local progression of cutaneous melanoma,[304] as well as polyoma middle T antigen–induced vascular tumors.[305] The absence of TAFI, on the other hand, does not appear to alter the progression of primary Lewis lung carcinoma, B16 melanoma, or T241 sarcoma tumors or their metastases.[306]

PAI-1 has a surprising stimulatory effect on the growth and invasiveness of murine tumors derived from malignant keratinocytes. In PAI-1–deficient mice, these tumors are subject to loss of local invasion and tumor vascularity,[307] thus suggesting that PAI-1 may play an adhesive rather than an anticatalytic role in this system. Similarly, murine fibrosarcoma cells implanted in PAI-1$^{-/-}$ mice display reduced tumor cell proliferation and neovascularization.[303] On the other hand, neither tumor cell burden nor overall host survival were affected by the absence of PAI-1 in a murine model of metastatic melanoma.[259] Thus the precise role of PAI-1 in tumor biology may depend critically on the specific context.

Microbial Virulence and Host Defense Mechanisms

There is increasing evidence that pathogenic bacteria can usurp elements of the host fibrinolytic system to enhance their own virulence.[308,309] In Lyme disease, for example, dissemination of *Borrelia burgdorferi* in both the tick vector and the mammalian host requires that the spirochete bind host plasminogen and use host plasminogen activator.[310] Similarly, *Borrelia* species employ host plasminogen for heart and brain invasion in relapsing fever.[311] Plasminogen-deficient mice also appear to be remarkably resistant to *Yersinia pestis*, whose own plasminogen activator (Pla) is required for the rapid progression of primary pneumonic plague.[311,312,313] Expression of human plasminogen in mice overrides their natural resistance to invasive infection with group A β-hemolytic streptococci.[314]

Components of the fibrinolytic system are required for the recruitment of host cells to sites of inflammation. In plasminogen-null mice, for example, the influx of neutrophils to the peritoneum in response to thioglycolate is normal, whereas recruitment of lymphocytes and monocytes is significantly impaired.[315] In the murine lung, similarly, recruitment of phagocytes and lymphocytes in response to *Cryptococcus neoformans*[316] and *Pneumocystis carinii*[317] requires uPA. Recruitment of neutrophils in response to *Pseudomonas aeruginosa*, on the other hand, depends on uPAR but not on uPA, thus suggesting a nonfibrinolytic, possibly adhesive role for this receptor.[318]

Neurologic Plasticity

tPA appears to play a relatively unique role in modulating plasticity and cell death within the central nervous system. tPA, which is stored within neuronal cells, is released on calcium-mediated membrane depolarization[319] and participates in the immediate early response after electrical or pharmacologic stimulation of hippocampal neurons.[319,320] tPA expression is induced in Purkinje neurons after cerebellar motor learning,[321] and excessive tPA-related proteolytic activity in granule neurons may contribute to neuronal death in the weaver mouse cerebellum.[322] tPA-deficient mice do not display discernible motor or sensory deficiencies but do exhibit a mild defect in long-term potentiation.[323,324] These animals are resistant to excitotoxic neuronal degeneration in the hippocampus, in which plasmin-catalyzed degradation of laminin is blocked both by tPA deficiency and by infusion of a plasmin inhibitor.[325] In addition, tPA-deficient mice displayed diminished central nervous system signaling and behavioral responses to cocaine,[326] and tPA-deficient mice were also protected from the NMDA-mediated toxicities of ethanol in a model of fetal alcohol syndrome.[327]

Neuronal migration within the cerebellum of the developing mouse brain is reduced by approximately 50% in tPA-deficient mice,[328] and these animals exhibit increased sensitivity to the locomotor effects of cocaine.[329] During the remodeling of neuronal connections that occurs in response to seizure activity in the hippocampus, mice lacking either tPA or plasminogen show decreased mossy fiber outgrowth in this region and accumulate an extracellular matrix component known as DSD-1-PG/phosphacan. These data suggest both plasmin-dependent and plasmin-independent roles for tPA in neuronal plasticity.[330]

In both ischemic and hemorrhagic stroke, infusion of tPA can have a major effect on clinical outcome. After ischemic stroke in mice, tPA increases infarct size in both wild-type and tPA-null animals,[331] and smaller infarcts are observed in untreated tPA-deficient animals than in uPA-deficient or wild-type mice. Interestingly, the largest infarcts in the latter study were found in PAI-1$^{-/-}$ mice.[332] In a thrombotic stroke model, on the other hand, deficiency of tPA leads to more extensive vascular fibrin deposition and cerebrovascular thrombosis and consequently a sixfold to eightfold increase in infarct volume.[333]

Engagement of LRP by the tPA–PAI-1 complex may regulate the vascular response to injury by triggering NF-κB–mediated release and activation of matrix metalloproteinase 9 (MMP-9), which may lead to weakening of the blood-brain barrier and catastrophic hemorrhage.

In a mouse model, this process was inhibited by concomitant infusion of activated protein C, which by interacting with endothelial protein C receptor or protease activated receptor 1, or both, blocked the activation of NF-κB and hence release of metalloproteinase.[334] Together these data suggest that the actions of tPA in the central nervous system extend beyond the activation of plasmin.

NON–PLASMIN-MEDIATED FIBRINOLYSIS

There is accumulating evidence that proteases other than the traditional members of the fibrinolytic family may participate in fibrinolysis. Fibrin appears to be subject to degradation by activated monocytoid cells that express intracellular cathepsins.[335] In addition, MMP-3, MMP-7, and membrane type 1 MMP may cleave fibrinogen and cross-linked fibrin into fragments similar to those produced by plasmin.[336] Matrix MMPs have been shown to act as pericellular fibrinolysins, thereby providing an alternative pathway for fibrin-based angiogenesis in a plasminogen-free milieu.[337] In particular, membrane-type matrix MMPs appear to function in this way within a three-dimensional fibrin meshwork.[338]

  This paper showed for the first time that host plasminogen is usurped by Lyme disease spirochetes during infection.

312. Lathem WW, Price PA, Miller VL, et al: A plasminogen-activating protease specifically controls the development of primary pneumonic plague. *Science* 315:509–513, 2007.

  This paper showed for the first time that the plague enterobacterium produces a plasminogen activator that exploits host plasminogen to effect plasmin-dependent tissue invasion.

314. Sun H, Ringdahl U, Homeister JW, et al: Plasminogen is a critical host pathogenicity factor for group A streptococcal infection. *Science* 305:1283–1286, 2004.

  This paper showed that streptococci pirate host plasminogen to promote infection.

320. Qian Z, Gilbert ME, Colicos MA, et al: Tissue-plasminogen activator is induced as an immediate-early gene during seizure, kindling and long-term potentiation. *Nature* 361:453–457, 1993.

  This paper showed for the first time that tPA participates in neuronal adaptation that underlies memory and learning.

325. Chen ZL, Strickland SE: Neuronal death in the hippocampus is promoted by plasmin-catalyzed degradation of laminin. *Cell* 91:917–925, 1997.

  This paper revealed that injury-induced neuronal cell death in hippocampus can involve plasmin induced disadhesion to extracellular laminin.

331. Wang YF, Tsirka SE, Strickland S, et al: Tissue plasminogen activator (tPA) increases neuronal damage after focal cerebral ischemia in wild-type and tPA-deficient mice. *Nat Med* 4:228–231, 1998.

  This paper pointed out that treatment of cerebral thrombosis with tPA may increase brain-tissue injury.

337. Hiraoka N, Allen E, Apel IJ, et al: Matrix metalloproteinases regulate neovascularization by acting as pericellular fibrinolysins. *Cell* 95:365–377, 1998.

  This paper showed that matrix metalloproteinases may act as surrogate proteases in fibrinolysis.

CHAPTER 29

Approach to the Child with a Suspected Bleeding Disorder

Brian Branchford and **Jorge Di Paola**

CHAPTER OUTLINE

INTRODUCTION
CLINICAL EVALUATION
Clinical Presentation of Bleeding
Relevant Clinical History
Age of Onset
Family Bleeding History
Medications
PHYSICAL EXAMINATION
LABORATORY EVALUATION
Sample Collection and Technique and Preanalytical Variables
Screening Tests
Global Tests for the Evaluation of Bleeding
BLEEDING IN THE CRITICALLY ILL CHILD

INTRODUCTION

Before initiating the laboratory workup of any patient with a suspected defect of hemostasis, the hematologist must first verify that the patient has a clinical history, signs, and symptoms compatible with a bleeding disorder. This is not an easy task because mild bleeding and bruising are common in the general population. Furthermore, bleeding, particularly in the outpatient setting, is difficult to quantify because patient reports may be biased; the definition of "excessive" bleeding or bruising is subjective and varies among individuals. Additionally, a critical consideration in children is the fact that many of them have not had specific hemostatic challenges such as surgeries or menarche that might unveil a bleeding disorder. All these factors contribute to the difficulty in the diagnosis of bleeding in the pediatric population.

Therefore, an accurate diagnosis is made primarily by obtaining a thorough personal and family history and then performing a careful physical examination, which will lead to an appropriate set of laboratory tests. Once suspicion for a bleeding disorder is confirmed, the remaining workup items are implemented in a focused manner with reference to particular differential diagnoses.

Children with suspected bleeding disorders might present for evaluation in a variety of ways: concerning signs and symptoms, abnormal presurgical screening laboratory results, or a known family history of hemostasis defects that requires consultation. The variety in severity of different bleeding disorders also results in children presenting at different ages. The goal for the consulting hematologist is to approach the child with a broad differential diagnosis in mind, narrow the options by carefully assessing the medical and family history as well as pertinent physical findings, and order the most appropriate laboratory tests to reach a diagnosis and initiate definitive therapy, if indicated.

Although the approach to the bleeding child is often similar in the outpatient and inpatient setting, the practicing hematologist is sometimes consulted because of bleeding in the critically ill patient. In such cases therapeutic measures will likely be required immediately and an accurate diagnosis made later.

CLINICAL EVALUATION

The initial clinical evaluation of a child with a suspected bleeding disorder starts with a series of questions, usually at a doctor's office or clinic, that attempt to summarize the most important aspects of the clinical presentation and history of bleeding. Although several standardized bleeding assessment tools have been used recently in research projects, their value in clinical practice is still unproven. Therefore, questions should be designed to establish certain parameters that would prompt an appropriate laboratory workup. The initial set of questions should establish the following: (1) the most common site and type of bleeding (e.g., mucocutaneous versus articular or deep muscle), (2) bleeding on hemostatic challenge such as surgeries or trauma, and (3) family history of bleeding.

TABLE 29-1 Differences in Clinical Manifestations of Primary Hemostatic Defects and Clotting Factor Deficiencies

Clinical Characteristic	Primary Hemostatic Defect	Clotting Factor Deficiency
Site of bleeding	Skin, mucous membranes	Soft tissues, muscles, joints
Bleeding after minor cuts	Yes	Rare
Petechiae	Present	Absent
Ecchymosis	Small, superficial	Large, deep, palpable
Hemarthrosis	Rare	Common
Bleeding after trauma/surgery	Immediate	Delayed

Clinical Presentation of Bleeding

Significant surgical or postoperative hemorrhage, rectal or genitourinary bleeding, and major muscle or joint bleeding are easily identified as abnormal, but they represent a minority of new cases. Most often the clinician's challenge consists in differentiating mild but common presenting symptoms of bleeding disorders, such as easy bruising and mucosal bleeding (e.g., epistaxis, menorrhagia, oropharyngeal), from those encountered in healthy children and then determining when additional laboratory evaluation is warranted. Large bruises without previous significant trauma, disseminated petechiae, intramuscular hematomas, hemarthrosis (joint effusion, warmth, and pain with passive movement) usually indicate a bleeding disorder. In young children, refusal to walk is often a sign for an extremity-related bleed and could represent the first sign of hemarthrosis in a boy with hemophilia (Table 29-1).

Susceptibility to increased bruising must first be differentiated from nonmedical causes such as abuse, a phenomenon that is, unfortunately, common enough to warrant its own set of guidelines for evaluation in recent reports from the American Academy of Pediatrics.[1,2] Inflicted trauma is most likely to manifest over the head, chest, back, and long bones (and may retain the outlines of the instrument used to inflict harm), whereas bruises associated with primary hemostasis defects are usually located over areas of typical childhood trauma, such as bony protuberances of extremities or spinous processes.[3]

Epistaxis is a frequent presenting sign in children with hemostatic disorders, but it is also a common complaint among healthy children, usually the result of local aggravating factors (dry nasal mucosa, trauma, allergic rhinitis).[4] In a recent study of 248 children referred to the otolaryngology clinic at Children's Hospital of Philadelphia for epistaxis, 11% were found to have a bleeding disorder (type 1 von Willebrand disease [VWD], platelet aggregation defect, or mild factor VII deficiency), with clinical predictive factors being younger age or previous emergency medical care for the epistaxis.[5] Other studies, however, have found an incidence as high as 25%[6] to 33%[7] for coagulopathy among children referred to pediatric hematologists for recurrent epistaxis. Therefore it is important that epistaxis be taken seriously as a presenting symptom, particularly in cases that require emergency medical care, occur in both nostrils, or appear in association with other bleeding signs or a family history of similar bleeding.

Menorrhagia is also a frequent presenting sign for mild or moderate bleeding disorders (including VWD, platelet function disorders, and other coagulopathies)[3] and can quickly lead to severe anemia and decreased quality of life. The classic definition of menorrhagia (i.e., greater than 80 mL of blood loss per cycle) is rarely used clinically[8] because most women describe limitations of their daily activities as more important than the actual volume of blood lost.[9] A more popular working definition is "excessive cyclic uterine bleeding that occurs at regular intervals over several cycles, or prolonged bleeding that lasts for more than 7 days".[10] In fact, the American College of Obstetrics and Gynecology has recommended that testing for VWD be performed in all adolescents with severe menorrhagia,[11] although a subsequent meta-analysis determined that there may not be adequate data to support this universal recommendation.[12] It is essential for practitioners to be judicious about laboratory testing in adolescents with menorrhagia. All adolescents that present with menorrhagia should be evaluated by a gynecologist; testing for a bleeding disorder is not always warranted, particularly in the absence of family and personal history or other bleeding manifestations.

Surgical (e.g., circumcision, tonsillectomy) or dental (e.g., extractions) bleeding also may be associated with disorders of hemostasis. This type usually manifests as uncontrolled bleeding during or after the procedure, bleeding that extends beyond the surgical site, unexpected need for blood transfusion, or delayed bleeding after a procedure.[3]

Hereditary hemorrhagic telangiectasia may also be manifested as mucosal bleeding, particularly epistaxis. Profuse bleeding into soft tissues or joints suggests deficiency of a coagulation factor (such as factors VIII or IX). Umbilical stump bleeding is typically seen with factor XIII deficiency, but it may also occur with deficiencies of prothrombin, factor X, and fibrinogen.[13]

After establishing the possibility of a true bleeding disorder, the clinician should next consider a broad differential diagnosis for the bleeding child and approach the history taking and physical examination with the intent to systematically remove options and pare down the list to a certain category or group of potential diseases. Briefly, the main categories to be considered should include anatomic abnormalities, quantitative and qualitative platelet defects affecting platelet plug formation (primary hemostasis), and quantitative and qualitative defects of clot propagation (secondary hemostasis). Differentiation also must be made between inherited and acquired disorders. Common diseases should be considered before rare ones, and diagnoses that are either life threatening or easy to treat should be prioritized in the evaluation process.

Finally, it is clear that the clinical assessment and the laboratory workup of the bleeding child will vary depending on the emergent nature of the clinical situation. The practicing hematologist is often consulted in the inpatient setting regarding bleeding in the intensive care unit or operating room. The approach in these situations is sometimes limited by the inability to obtain reliable baseline hemostatic laboratory values because of the presence of active disease or the fact that most patients receive hemostatic agents (including blood products) to stop the hemorrhage. Therefore it becomes difficult to distinguish congenital bleeding conditions frin acquired ones. Often the immediate need for treatment supersedes a more thorough evaluation. In these cases it is reasonable to treat the patient and then, if a baseline defect of hemostasis is suspected, perform the laboratory evaluation days or even months after the episode, when the acute process is resolved.

Relevant Clinical History

Information about the patient's previous response to hemostatic challenges (e.g., surgical procedures, invasive dental work, traumatic injuries) is an essential part of the initial evaluation. For example, a congenital hemorrhagic disorder is unlikely in a patient with a history of surgical procedures or tooth extractions without any abnormal bleeding, whereas postoperative transfusion requirements and iron-responsive anemia often signal hemostatic defects. In view of the variability of patients' perception of bleeding, as well as the lack of a uniform clinical measure of bleeding severity, the history may be most discriminatory when a standardized and validated questionnaire is used and a "bleeding score" is incorporated into the diagnosis.[14,15] Several such instruments currently exist, but consensus on a single questionnaire that can quantitate bleeding optimally is still evolving.[16-18] The International Society of Thrombosis and Hemostasis (ISTH) Joint Scientific Subcommittee (SSC) on von Willebrand factor (VWF) and Pediatric/Perinatal Bleeding Disorders recently developed a bleeding assessment tool to provide more accurate determination of bleeding phenotype in individuals with bleeding disorders and compared them to healthy subjects.[19] The main objective of all the existing bleeding assessment tools is to accurately diagnose bleeding and predict the risk of bleeding in the future. However, owing to their high negative predictive value, it is becoming increasingly clear that these new instruments are more effective at excluding the likelihood of a bleeding disorder than predicting future bleeding risk. Family history is also a key component in establishing both the likelihood of an inherited bleeding disorder and its specific nature. However, determination of which family members may have been affected by relying on testimony from one or more relatives can be difficult. Therefore the ISTH SSC on VWF has a specific definition of a positive family history for VWD.[20] In summary, a personal history of bleeding triggers clinical and laboratory evaluation, and a positive family history serves as supportive evidence for a hereditary bleeding disorder.[21]

The history of the present illness often provides useful clues to the diagnosis, including several classic types of presentation. A sick child with fever, shock, and mucocutaneous purpura may have disseminated intravascular coagulation (DIC) associated with bacteremia. Hemophilia should be considered in a male toddler who has just started crawling and exhibits subcutaneous or joint bleeding, or who bleeds after circumcision. A girl who has had severe menorrhagia since menarche may have VWD. A well-appearing child covered with petechiae likely has immune thrombocytopenia, but if the lesions are localized to the buttocks, ankles, and feet, and they present as palpable bruises, Henoch-Schönlein purpura should be considered.

When applicable, a detailed menstrual history, including age at menarche, duration of menses, interval between menses, and frequency of pad or tampon replacement necessary to control the bleeding, should be obtained. The prevalence of bleeding disorders in women with menorrhagia is as high as 20%, and menorrhagia is a common initial symptom in women with VWD (approximately 90% of female patients).[22-26]

It is also important to note whether the patient has an underlying medical disorder that may affect hemostasis, such as hepatic or renal disease, malabsorption syndrome, or Ehlers-Danlos syndrome (EDS) or another connective tissue disorder.[27] Most of the coagulation proteins are synthesized in the liver, and as a result, liver insufficiency is a common cause of prolongation of clotting times and bleeding.[28,29] Certain metabolites that accumulate in uremia can interfere with platelet function,[30,31] whereas low-molecular-weight coagulation proteins (factors IX and XI) are lost through the kidney in children with nephrotic syndrome.[32] In malabsorption syndrome, levels of the vitamin K–dependent coagulation factors (II, VII, IX, and X) may be depleted and lead to excessive bleeding.[33,34] A child with cyanotic congenital heart disease and polycythemia may have petechiae and excessive bleeding with surgery, in part as a result of thrombocytopenia, hypofibrinogenemia, or both.[35]

Age of Onset

It is also important to investigate the age of onset of clinical bleeding. Generally, early age of onset correlates with more severe bleeding and may indicate a congenital cause. Bleeding that develops later in childhood may indicate either an acquired problem or a milder congenital bleeding disorder. For example, mild hemophilia may not be diagnosed until late childhood or adolescence, when participation in contact sports presents an increased hemostatic challenge.[36,37] Postcircumcision hemorrhage, umbilical stump bleeding, cephalohematomas, and subgaleal hemorrhage are cardinal manifestations of underlying bleeding disorders and should be evaluated thoroughly. The incidence of neonatal intracranial hemorrhage among boys with hemophilia is estimated to be as high as 3% and may be as high as 25% in patients with FXIII deficiency.[3]

The neonatal period (first 4 weeks after delivery) is a time of unique transitional physiology, which includes the coagulation system. The neonate has physiologically decreased levels of most procoagulant and anticoagulant proteins (although levels of acute phase reactants, such as factor VIII and fibrinogen, are normal), and thus the hemostatic system can be easily overwhelmed, potentially during the significant head trauma associated with labor and vaginal delivery. One study reported intracranial hemorrhage (ICH) after spontaneous vaginal delivery at a rate of 1 per 1900, whereas the rate of ICH in babies delivered by vacuum-assisted delivery was 1 in 860.[38] In addition, 15% to 30% of patients with inherited bleeding disorders have bleeding manifestations in the neonatal period,[39] and certain disorders, such as neonatal alloimmune thrombocytopenia (NAIT), are unique to the neonatal period. Furthermore, the neonate is significantly affected by the state of maternal health and medications used during labor. Because of the small blood volume in a neonate, a relatively small degree of blood loss can have major hemodynamic consequences.

When evaluating bleeding in a neonate, the hematologist must first assess whether the baby is healthy or has medical conditions that may have precipitated hemorrhage. It is important to inquire about prolonged rupture of membranes, chorioamnionitis, and fetal distress during labor. Additional details about the mother's state of health, including infections, autoimmune disease, and platelet count, should be obtained. Vitamin K administration to the baby should be confirmed. The neonate should be examined, with particular attention directed to the presence of birth trauma, bruises, and petechiae and evidence of flank masses (renal vein thrombosis), which can cause thrombocytopenia. The presence of hepatosplenomegaly may suggest disseminated intrauterine infection. When blood is obtained for various coagulation tests, particular attention should be paid to the patient's hematocrit concentration and the volume of the sample. Additionally, all laboratory results should be compared with normal values for different gestational ages.[40,41]

Isolated thrombocytopenia in a healthy infant may be seen in NAIT, in maternal autoimmune thrombocytopenia, or in cases of decreased platelet production such as amegakaryocytic thrombocytopenia or the syndrome of thrombocytopenia with absent radii. Rarely, type 2B VWD may be manifested as thrombocytopenia in a well infant. Thrombocytopenia in sick neonates is often due to the underlying cause, such as infection or DIC. Isolated prolongation of the prothrombin time (PT) or activated partial thromboplastin time (APTT) in a healthy baby may be caused by a specific clotting factor deficiency in the extrinsic or intrinsic pathway, respectively, and prolongation of both the PT and APTT suggests either a common pathway clotting factor deficiency or vitamin K deficiency (hemorrhagic disease of the newborn). The so-called early vitamin K deficiency–associated bleeding usually presents in the first week of life and is associated with nutritional deficiencies or failure to administer vitamin K at birth, whereas late vitamin K deficiency bleeding occurs between 3 and 8 weeks after birth and may manifest as intracranial hemorrhage or severe gastrointestinal bleeding.[42]

Family Bleeding History

The family history is essential for assessing differential diagnoses. The hematologist should inquire about any known or suspected bleeding problems in other family members, including any specific diagnoses. If the family history is positive for bleeding, the hematologist should note the type and severity of bleeding (e.g., joint bleeding, epistaxis, menorrhagia), age at onset, and the relationship of the affected family member or members to the patient. An X-linked recessive inheritance pattern (maternal cousins, uncles, and grandfather) suggests a diagnosis of hemophilia A or B,[43] whereas an autosomal dominant pattern would be more consistent with VWD or hereditary hemorrhagic telangiectasia. Most other clinically relevant clotting factor deficiencies are inherited in an autosomal recessive manner, and the family history is frequently negative for bleeding, although consanguinity may be noted.

Approximately one third of infants and young children with newly diagnosed hemophilia have a negative family history,[3] consistent with the Haldane hypothesis for the fraction of new mutations in all lethal X-linked recessive disorders.[44,45] For VWD, considerable variation in symptoms may be noted among affected family members because of the incomplete penetrance (i.e., not every person that inherits the mutation will exhibit an abnormal phenotype) and variable expressivity (i.e., family members with the same mutation have a variable phenotype) that are hallmarks of this disease. Bleeding manifestations may be very mild in some and give the misleading impression of a negative family history. Factor XI deficiency, an autosomal trait most often (but not exclusively) seen in persons of Ashkenazi Jewish descent, may be associated with a very mild or moderate tendency for bleeding. The degree of bleeding manifestations does not correlate well with the level of factor XI or the APTT, although the patient's specific mutation may be predictive.[46,47]

Medications

A careful history of medication use should be obtained, including prescribed medications, over-the-counter drugs, recreational drugs, and herbal products.[48] A number of drugs are associated with bleeding diatheses, with mechanisms including induction of thrombocytopenia (e.g., quinine or quinidine, rifampin, trimethoprim-sulfamethoxazole, carbamazepine, cimetidine, ranitidine, valproic acid)[49-52] and platelet dysfunction (nonsteroidal antiinflammatory drugs [NSAIDs] such as ibuprofen [reversible effect] and aspirin [irreversible]).[53,54-57] In the case of medications that cause platelet dysfunction, it is important to note that they primarily exacerbate preexisting bleeding disorders rather than cause clinically relevant bleeding by themselves. In addition, prolonged antibiotic use may lead to lower vitamin K levels and induce bleeding secondary to acquired deficiency of vitamin K–dependent factors. Table 29-2 lists medications, compounds, and herbal supplements known to be associated with bleeding.

PHYSICAL EXAMINATION

A thorough physical examination must begin with an evaluation of the vital signs, with particular emphasis on

TABLE 29-2 Compounds that Decrease Platelet Number and/or Function

Effect	Compound Class	Examples	Mechanism
Platelet dysfunction	COX-1 inhibitors	Aspirin, ibuprofen, naproxen	Inhibit conversion of AA to thromboxane A2
	Thienopyridines	Clopidogrel, prasugrel, ticagrelor, cangrelor	Inhibit ADP-induced platelet activation
	Phosphodiesterase inhibitors	Dipyridamole, cilostazol	Increased cAMP decreases agonist-induced activation
	GPIIb/IIIa inhibitors	Abciximab, tirofiban, eptifibatide	Inhibit integrin activation and conformational change
	β-Lactam antibiotics	Cephalosporins, penicillins (esp. in high doses)	Inhibit epinephrine- and ADP-induced aggregation and granule release. Also, interference with platelet-VWF interaction
	SSRIs	Fluoxetine, olanzapine, citalopram, sertraline, escitalopram	Decrease platelet serotonin
	Herbs and foods	Ginkgo *(Ginkgo biloba)* Garlic *(Allium sativum)* Bilberry *(Vaccinium myrtillus)* Ginger *(Zingiber officinale)* Dong quai *(Angelica sinensis)* Feverfew *(Tanacetum parthenium)* Asian ginseng *(Panax ginseng)* American ginseng *(Panax quinquefolius)* Siberian ginseng/eleuthero *(Eleutherococcus senticosus)* Turmeric *(Curcuma longa)* Meadowsweet *(Filipendula ulmaria)* Willow *(Salix alba)* Black tree fungus *(Auricularia polytricha)*	Various
	Alcohol	Alcohol	Decrease P-selectin exposure
	Other	Amitriptyline, imipramine, chlorpromazine, cocaine, lidocaine, isoproterenol propranolol, penicillin, ampicillin, cephalothin, promethazine, diphenhydramine, carbenicillin	Interfere with platelet membrane
		Furosemide, verapamil, hydralazine, cyclosporine, hydrocortisone	Inhibit prostaglandin pathways
		Caffeine, dipyridamole, aminophylline, theophylline, vinblastine, vincristine, colchicine, papaverine	Inhibit platelet phosphodiesterase
Thrombocytopenia	Antiepileptic drugs	Phenytoin, valproate, carbamazepine	Unclear
	Glycoprotein IIB/IIIa inhibitors	Abciximab	Drug-dependent antibody
	Anticoagulants	Unfractionated heparin (more common) low-molecular-weight heparin (less common)	Drug-dependent antibody
	Foods	Quinine, white lupin, tahini, jui herbal tea	Various

AA, Arachidonic acid; *A2*, annexin 2; *ADP*, adenosine diphosphate; *cAMP*, cyclic adenosine monophosphate; COX, cyclooxygenase-1; GP, glycoprotein; SSRI, selective serotonin reuptake inhibitors; VWF, von Willebrand factor.

potential signs of severe bleeding-related anemia or intravascular volume loss, such as tachycardia (early finding) or hypotension (late finding). Next, a global overview should be undertaken to observe the pattern of bleeding stigmata. Petechiae are small capillary hemorrhages and characteristically develop in crops in areas of increased venous pressure, such as dependent parts of the body or those compressed by elastic waistbands, sock tops, or straps (e.g., from backpacks, purses, luggage). They are painless, nonpalpable, and nonblanching and must be distinguished from small telangiectases and angiomas. In general, the presence of petechiae indicates a defect in primary hemostasis (platelet number or function or vascular integrity). Ecchymoses are palpable purplish lesions induced by subcutaneous bleeding and usually indicate a defect in secondary hemostasis (clot propagation), such as deficiency of a coagulation factor. Additionally, hemarthrosis, associated with severe coagulation factor deficiency, should be evaluated for joint size, swelling, and range of motion limitations. Identification of hepatomegaly and splenic enlargement may point toward coagulopathy associated with systemic disorders such as leukemia or hepatocellular disease.

Knowledge of the bleeding manifestations of certain syndromes can help the hematologist efficiently evaluate children with known syndromes. Conversely, the hematologist's identification of a particular bleeding pattern may pave the way to an important syndrome diagnosis that can guide other system-based evaluation or interventions earlier than would otherwise be possible. For example, it is important for the hematologist to know that patients with Noonan syndrome can have thrombocytopenia, platelet function defects, and prolonged APTTs secondary to abnormalities of the intrinsic pathway (deficiencies of FVIII, FIX, FXI).[58,59] Another example is the importance of recognizing bleeding related to skin or vascular fragility as a potential manifestation of heritable connective tissue disorders such as EDS.[27] The molecular basis for bleeding in these syndromes is not well understood, but the clinical association between these syndromes and excessive hemorrhage is strong enough to warrant a careful investigation.

LABORATORY EVALUATION

Sample Collection and Technique and Preanalytical Variables

A properly drawn blood sample is crucial for adequate interpretation of coagulation test results.[60,61] Many laboratories develop independent ranges, controlling for preanalytic variables (patient posture, medical condition, lipid levels, hormones, mental and physical stress, activity before blood draw, tourniquet time, proper tube filling, specimen processing, and transport conditions).[62] Preferably, subjects should be fasting and should have refrained from smoking, caffeine, or alcohol ingestion, and they should not have taken any medications known to affect platelet function (see Table 29-2) on the day of testing; for some medications, such as aspirin and NSAIDs, the period of abstinence should be at least 2 weeks.[63] Herbal remedies, garlic, and alcohol may also cause acquired mild platelet dysfunction.[53] Blood for coagulation assays should be obtained by venipuncture performed by an experienced phlebotomist using a 19- to 21-gauge needle.[60,61] Drawing samples from an indwelling catheter often results in sample contamination with heparin or intravenous fluids and spuriously abnormal values. Improper sample collection is one of the most common reasons for falsely prolonged clotting times.[64-66] The total tourniquet time should be less than 3 minutes.[67]

The initial 1 to 2 mL of blood should be drawn into a waste tube to prevent activation of the test sample by tissue factor. Then blood is collected into citrated anticoagulant in an evacuated sample tube containing a fixed amount of buffered sodium citrate (3.2% preferred over 3.8% for coagulation assays) as anticoagulant in the ratio of one part citrate to nine parts whole blood.[63,68,69] A clinically significant difference between glass and plastic tubes has not been identified.[70] If the patient is polycythemic (hematocrit ≥55%), the amount of plasma in the tube would be reduced in proportion to the citrate, thereby leading to falsely abnormal coagulation test results. In such circumstances the amount of citrated anticoagulant should be reduced proportionate to the high hematocrit.[71,72] Conversely, anemia (hematocrit <25%) does not seem to significantly affect the accuracy of coagulation tests,[73] but it does have an effect on some global assays of hemostasis such as the Platelet Function Analyzer (PFA-100) in which hemoglobin should be greater than 10 mg/dL (and platelets should be >100,000/μL) to provide proper biorheologic effect to bring platelets in contact with the agonist-coated peripheral section of the device.[63] For infants and children, small 3-mL tubes (2.7 mL blood to 0.3 mL citrate) are available. Tubes of all sizes should be filled to at least 90% of the expected fill volume to prevent false elevation of clotting times from a disproportionately high citrate level. When tubes with various anticoagulant types are used, the citrate tubes should be collected before ethylenediaminetetraacetic acid–containing or heparin-containing tubes to avoid the potential for carryover.[69]

Once the tube is filled, the anticoagulated blood should be gently mixed by inversion three to four times, sent to a special coagulation laboratory without delay, and tested within 2 hours of collection if maintained at room temperature or within 4 hours if kept cold. Samples with visible hemolysis or clots should be discarded. Plasma samples must be frozen if they are not tested within this time frame. When they are to be analyzed, frozen samples should be rapidly thawed at 37° C and tested immediately. Normal values differ from one laboratory to another and between instruments and reagents. Thus the values obtained should be compared with the age-appropriate normal range for that particular laboratory.

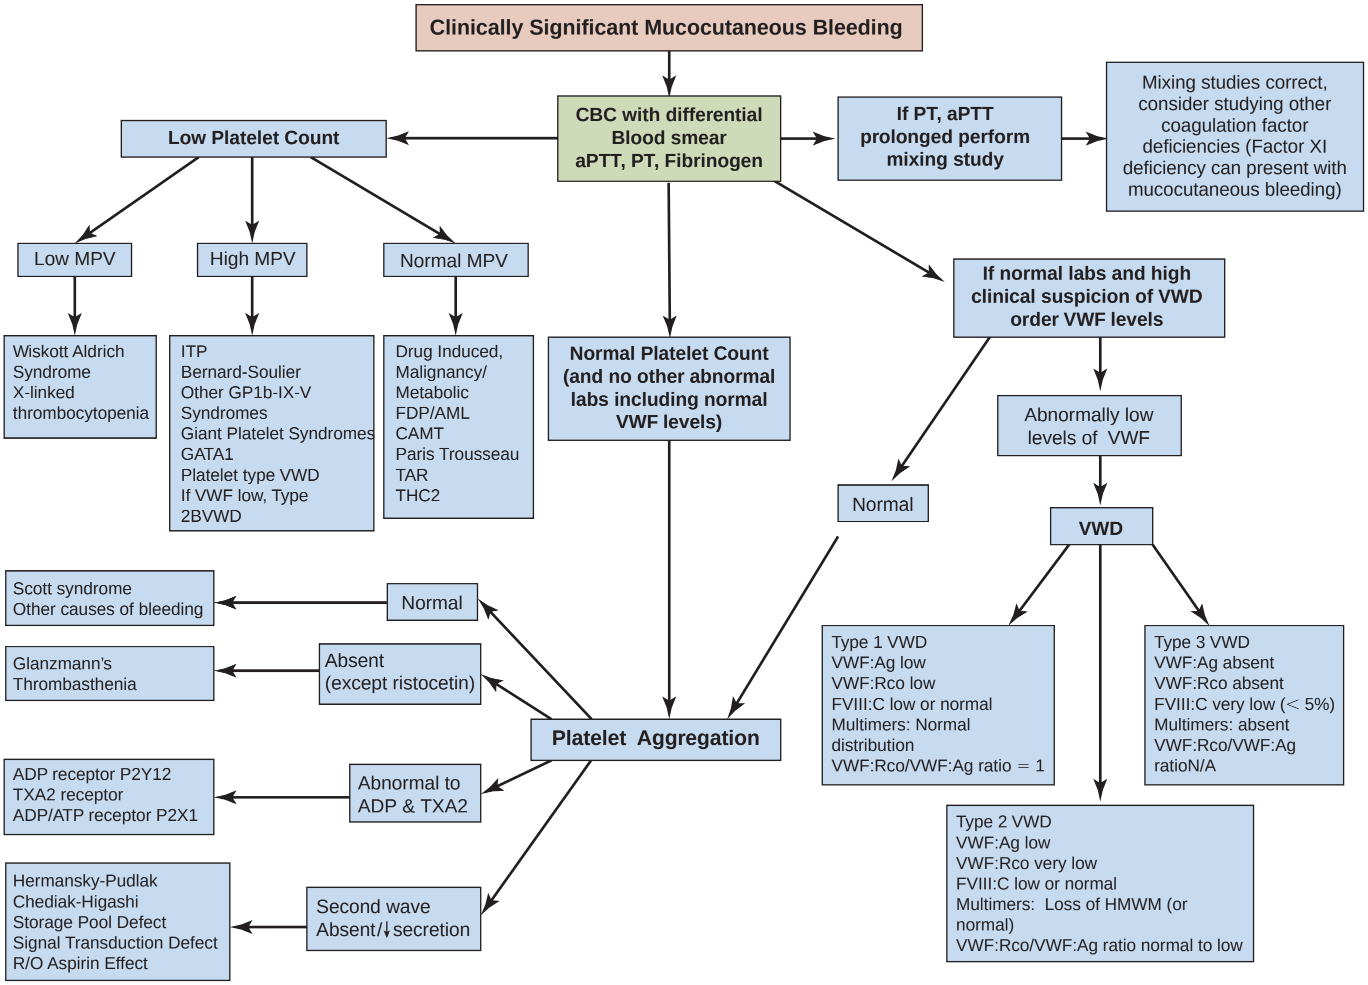
Screening Tests

A focused history and physical examination may lead the physician to obtain certain assays immediately, in order to identify common disorders, life-threatening situations, or easily treated conditions. However, if the initial evaluation does not suggest a specific disorder, a panel of screening tests should be ordered, including a complete blood count with evaluation of platelet number, size, morphology, PT, APTT, and thrombin time (TT) to help in the process of differential diagnosis. Although screening tests represent a very important part of the initial laboratory evaluation, they are usually neither predictive nor confirmatory of bleeding. Therefore, if a specific bleeding disorder is suspected, the laboratory evaluation should be directed to that specific disorder. These principles are illustrated in Figure 29-1, which provides an algorithm representing the general approach to working up clinically significant mucocutaneous bleeding.

Prothrombin Time

The PT is performed by adding a thromboplastin reagent that contains calcium chloride to the citrated plasma sample. The time required for clot formation is recorded with an automated instrument that signals the end point, as defined by optical or electromechanical change. The normal (reference) range varies depending on the laboratory (its instrumentation and the lot of thromboplastin), but it is generally 10 to 11 seconds. The PT measures the activities of factors I (fibrinogen), II (prothrombin), V, VII, and X. Prolongation of the PT beyond the reference range is not generally seen until the functional level of one of these factors is less than 30% or until fibrinogen is less than 100 mg/dL. Isolated prolongation of the PT may reflect factor VII deficiency. Though rare, the PT can also be prolonged by a circulating inhibitor to one of the involved clotting factors or by the presence of abnormal fibrinogen molecules or fragments in the circulation.

The PT is also quite useful for monitoring the effect of coumarin-type anticoagulants. When the PT is used to monitor a patient taking warfarin, differences in the sensitivities of different thromboplastin preparations in different laboratories need to be taken into account. This consideration has led to the development of a



Clinically Significant Mucocutaneous Bleeding

standardized method of expressing the prolongation as an international normalized ratio.

Activated Partial Thromboplastin Time

The APTT is performed by adding a "partial thromboplastin" reagent, which is a source of phospholipids without tissue factor, to the patient's citrated plasma sample, plus introducing controlled activation of the contact factors (factors XI and XII, prekallikrein, and high-molecular-weight kininogen) by preincubation with a surface-activating reagent (e.g., Celite, kaolin, silica, or ellagic acid).[74] This mixture is incubated for 2 to 5 minutes before calcium chloride is added, and the time required for clot formation is recorded. As for the PT, automated instruments are generally used. The APTT measures factors I (fibrinogen), II (prothrombin), V, VIII, IX, X, XI, and XII; prekallikrein; and high-molecular-weight kininogen. Deficiency of any of the latter three factors can result in a markedly prolonged APTT in the absence of clinically significant bleeding. Isolated prolongation of the APTT in a patient with clinical bleeding is likely to result from a deficiency of factor VIII, IX, or XI. It should be noted that the sensitivity and reproducibility of the APTT are highly dependent on the specific reagents used (particularly the activator in the partial thromboplastin reagent). With most APTT reagents, the APTT will not be prolonged until the amount of factor VIII is less than 35% (0.35 U/mL). The laboratory should establish a reference range for each new lot of reagent and each new method of clot detection. The reference range will generally be approximately 26 to 35 seconds for children and adults but longer (30 to 54 seconds) in term infants (and often even longer in premature infants).

The APTT is somewhat less sensitive than the PT to deficiency of the vitamin K–dependent factors (so mild deficiencies could be missed), but it is more sensitive to the presence of circulating anticoagulants and heparin. The APTT can detect circulating anticoagulants (e.g., lupus anticoagulants) and is routinely used to monitor standard heparin therapy.[75] Among hospitalized infants or children, unintentional contamination of patient samples with heparin is a common cause of an unexpected prolongation of the APTT that does not correct on mixing.

Thrombin Time

The TT measures the thrombin-induced conversion of fibrinogen to fibrin and is performed by adding bovine thrombin to the patient's citrated plasma and recording the clotting time. The TT measures the amount and the clotting function of fibrinogen and is also prolonged in the presence of heparin or circulating fibrin degradation products (FDPs). An extremely prolonged TT usually indicates a heparin effect. Reptilase, a snake venom protease, clots fibrinogen in the presence of heparin and thus can be used to identify heparin as the cause of a prolonged TT. Thus in the presence of heparin the TT is prolonged, whereas the reptilase time is normal. Alternatively, it is possible to test for heparin activity by its anti–factor Xa activity or with the use of commercial heparinase. The sensitivity of the TT can be increased by dilution of the thrombin to give a control TT of 16 to 18 seconds.

Platelet Count

The normal platelet count (for all ages) ranges from 150,000 to 450,000 per microliter. Review of the platelets on a well-prepared stained blood smear should give a visual estimate that matches the laboratory's printed value. A spuriously low automated platelet count (pseudothrombocytopenia) may result from ethylenediaminetetraacetic acid anticoagulant plus an IgG or IgM platelet antibody, platelet cold agglutinins, unexpectedly large platelet size (e.g., as seen in idiopathic thrombocytopenia purpura) in which the cell counter is unable to distinguish the platelets from other cell types, or platelet clumping from a partially clotted sample. Electric particle counters also often provide a mean platelet volume and platelet volume (size) distribution. In the setting of thrombocytopenia, increased platelet size may suggest increased platelet turnover. Large platelets are also seen in many hereditary platelet syndromes, and very small platelets are characteristic of Wiskott-Aldrich syndrome.

Bleeding Time

The bleeding time (BT), a measurement of length of time that bleeding continues after a standardized wound is made on the forearm or ear lobe, is no longer in clinical use in the United States or United Kingdom, primarily because of its poor reliability and parental perception of the test as overly invasive. It is, however, inexpensive and uses moderately accessible materials, and therefore it is still used in developing countries as a global hemostasis assay.

PFA-100

Current platelet function tests are often viewed as inaccurate and unreliable (BT) or labor intensive and time consuming (platelet aggregation studies). Recently, a range of new instruments have been developed that attempt to simulate in vivo platelet adhesion and aggregation. The PFA-100 (Dade Behring, Marburg, Germany) is a commercially available instrument that uses test cartridges containing collagen/adenosine diphosphate- or collagen/epinephrine (CEPI)-coated membranes with a small aperture (150 μm). Citrated blood is aspirated under high shear (5000 to 6000/sec) from the sample reservoir through a capillary tube onto the membrane, and blood flow is monitored through the aperture. Platelets begin to adhere and aggregate primarily through interactions with collagen under high shear, thereby resulting in closure of the aperture. The instrument monitors the drop in flow rate with time as the aperture gradually occludes and records the final closure time (CT) with either cartridge. Although the test is reproducible between cartridge lots and instruments, each laboratory should establish normal control times. Citrate samples have been shown to be stable for up to 4 hours after sample collection, but transport through a pneumatic vacuum transport or "tube" system is not recommended.

The test is sensitive to the platelet count, hematocrit concentration, platelet function, and VWF level and function. Generally, a platelet count of less than 80 to 100 × ^{9}/L or a hematocrit concentration of less than 30% leads to a prolonged CT.[76] The PFA-100 CT is inversely proportional to the VWF levels and has been used by some as a screening test for VWD.[77] In congenital platelet disorders, PFA-100 CT depends on the severity of the disorder. Severe platelet function defects in glycoprotein Ib/V/IX (Bernard-Soulier syndrome or platelet-type VWD) and glycoprotein IIb/IIIa (Glanzmann thrombasthenia) result in a markedly prolonged CT. In platelet-dense granule deficiency or secretion defects, the prolongation in CT is variable and is often seen in the CEPI cartridge. Thus, although the PFA-100 CT is abnormal in some forms of platelet disorders, the test does not have sufficient sensitivity or specificity to be used as a screening tool for platelet disorders in general.[78] It is most consistently abnormal in severe platelet function disorders, in which clinical symptoms alone are significant enough to suggest the diagnosis. Additionally, PFA-100 CT may be altered by drugs that affect platelet function. Aspirin and other NSAIDs prolong the CEPI CT. The role of the PFA-100 in therapeutic monitoring is currently being investigated.[78] Despite its wide use, the PFA-100 has not demonstrated great overall efficacy as a screening tool for mild to moderate bleeding disorders.

Specific Tests

Specific Coagulation Factors. Each of the coagulation factors of the intrinsic pathway (prekallikrein, high-molecular-weight kininogen, and factors VIII, IX, XI, and XII) can be measured by one-stage, APTT-based methods. A specific factor assay measures the clotting time of a mixture of diluted test plasma and a specific factor-deficient substrate plasma that supplies all factors except the one being measured.[79] Though seldom performed in U.S. clinical laboratories, a chromogenic substrate assay kit for factor VIII (as well as chromogenic kits for certain other clotting factors) that is based on measuring the generation of factor Xa is also commercially available.

Each of the extrinsic and common pathway coagulation factors (V, VII, and X) can be measured by specific one-stage assays based on the PT. The patient's diluted test plasma is incubated with commercially available plasma that is deficient in either factor V, VII, or X; a mixture of tissue factor and calcium chloride is added, and the clotting time is determined.[79]

For each clotting factor assay based on the APTT or PT, the clotting times of serial dilutions of a plasma sample representing a pool obtained from a large number of normal individuals is used to construct a standard curve. The concentration of the specific factor in each of the several dilutions of patient plasma is determined from the standard curve and is used to calculate the level of that clotting factor in the patient's undiluted plasma.[79] In most laboratories, automated instruments are used to perform the assays, and many of these instruments are preprogrammed with a statistical package for plotting the data. The reference pooled normal plasma should be calibrated with a commercial or national standard that has been assayed against an international standard when available.[80]

Covalent stabilization of fibrin by factor XIIIa is essential for normal hemostasis (see Chapter 27). Factor XIIIa catalyzes the formation of covalent cross-links between the α and γ chains of fibrin, which results in increased mechanical stability of the fibrin clot and resistance to its degradation by plasmin. None of the routine screening tests (PT, APTT, or BT) detect factor XIII deficiency.[81] Screening for factor XIII deficiency can be performed with the clot solubility test: solubility of the patient's recalcified plasma clot in 5 mol/L urea or monochloroacetic acid is assessed after 30 minutes and periodically at 1, 2, 4, and 24 hours. Clots from patients with less than 1% factor XIII activity are soluble. Quantitation of factor XIII can be done with specific amine incorporation assays, although these tests are generally performed only in specialized research laboratories.[81]

Recommended tests for VWD include APTT, factor VIII assay, ristocetin cofactor assay to measure VWF activity, VWF antigen assay, and ABO blood group typing. If these tests suggest VWD, VWF multimer analysis should be performed. Treatment of VWD depends on accurate subtype diagnosis (see Chapter 31).

Fibrinogen. The concentration of fibrinogen in plasma can be measured immunologically (fibrinogen antigen) or by a chemical method in which the ability of fibrinogen to clot does not influence the assay. Normal fibrinogen antigen levels are between 200 to 400 mg/dL. Fibrinogen is an acute phase reactant, and elevated levels are commonly seen in stress or acute illness.

The level of functional fibrinogen or fibrinogen activity can also be measured. The von Clauss kinetic assay uses a dilute solution of patient plasma and an excess of thrombin, which makes fibrinogen the rate-limiting step in the clotting reaction.[82] The resulting clotting time in seconds is compared with a standard dilution curve to determine the concentration of clottable fibrinogen. Fibrinogen is decreased in congenital afibrinogenemia, hypofibrinogenemia, and consumptive states such as DIC. The assay is also sensitive to abnormalities in fibrinogen function (dysfibrinogenemia) or the presence of inhibitors of fibrin formation such as FDPs.

Euglobulin Clot Lysis Time. The euglobulin clot lysis time (ECLT) is a screening test for excessive fibrinolysis. It is performed by using the plasma euglobulin fraction prepared from fresh, citrated, platelet-poor plasma. After clot formation, lysis is measured. The normal ECLT is 60 to 300 minutes. It is shortened in conditions characterized by increased fibrinolysis (e.g. α_2-antiplasmin deficiency, plasminogen activator inhibitor 1 deficiency, or systemic fibrinolysis).

Platelet Function Tests. When ordering tests of platelet function, the physician must be aware that a wide variety of drugs can affect the platelet count and alter test results. Drugs such as aspirin irreversibly affect platelet function for the entire life span of the platelet (10 to 11 days). Thus tests of platelet function should be scheduled at a time when the individual has not taken any relevant drugs for at least 10 days.

The most common test of platelet function is platelet aggregometry. Platelet aggregation can be performed in whole blood by impedance technique or in platelet-rich plasma (PRP) by the turbidimetric technique. Whole blood platelet aggregation can be combined with release of adenosine triphosphate by using a lumi-aggregometer. A variety of platelet agonists (ristocetin, epinephrine, collagen, adenosine diphosphate (ADP), and arachidonic acid) can be added to an aliquot of the patient's sample. The rapidity and extent of platelet agglutination are detected by changes in optical density (PRP) or impedance (whole blood) and are graphically recorded for each agonist used.[83] In Glanzmann thrombasthenia, the patient's platelets will agglutinate normally with ristocetin but not at all with the addition of ADP, epinephrine, collagen, or arachidonic acid. In Bernard-Soulier syndrome, platelet agglutination will occur normally on addition of each of these agonists except ristocetin.[83]

Global Tests for the Evaluation of Bleeding

Over the last two decades, investigators and clinicians have attempted to develop global assays of hemostasis that would eventually be able to predict risk of bleeding as well as measure therapeutic efficacy of blood products and clotting factor replacement therapy. As knowledge of the coagulation system developed in the 1950s, specific assays were devised to measure the individual clotting factors. However, it soon became apparent that individual clotting factor assays were inadequate to assess the true nature of the hemostatic system. It was obvious that static end point laboratory tests such as the PT or APTT also did not accurately reflect the patient's overall hemostatic status and could not assess the dynamic clotting cascade. The common clinical observation that patients with hemophilia have great phenotypic variation in bleeding despite identical factor levels stresses this point. This has led to a revival of interest in global clotting assays. In addition, the development of technical innovations and computer-assisted methods of analysis has improved the reliability and reproducibility of global assays. Two such techniques are described here: thromboelastography (TEG) and thrombin generation assays (TGAs). TEG is usually performed on whole blood and quantitatively measures the dynamics of fibrin formation. TGAs are generally performed on plasma and measure thrombin formation.

Thromboelastography

Hartert first described TEG as a global test for blood coagulation more than 50 years ago.[84] TEG monitors the whole dynamic process of hemostasis from clot formation to its dissolution and also provides information about platelet function. TEG produces a continuous profile of the overall rheologic changes occurring during coagulation while using a small amount of whole blood. By processing the data, the viscoelastic changes occurring during whole blood clot formation can be transformed into a dynamic velocity profile that is then recorded as a tracing. Currently, reagent-modified TEG with various activators (tissue factor, kaolin) and inhibitors is used with the aim of accelerating the coagulation cascade and obtaining differential diagnostic information.[85] The two commonly used instruments are the TEG (Haemoscope Corp, Skokie, Illinois) and the rotating thromboelastometer ROTEM (Pentapharm, Munich, Germany).[86] Currently used primarily as tools to decrease transfusion requirements during cardiac[87] and hepatic surgery, these instruments are also being investigated as screening tools for bleeding disorders.[88,89]

Thrombin Generation Assays

TGAs have been used extensively in research laboratories but are cumbersome to perform.[90] A more recently developed test, calibrated automated thrombography (CAT), may be applicable to the routine clinical laboratory. CAT measures the concentration of thrombin in clotting plasma by monitoring the splitting of a fluorogenic substrate and comparing the results with known constant thrombin activity in a parallel nonclotting sample (control).[91] Application of TGAs is currently being investigated for monitoring of hemophilia treatment and anticoagulation therapy and as a means to better understand the differing clinical patterns in bleeding disorders.[92]

Overall, although significant advances have been made in the development of global assays of hemostasis, and some of them are widely used in the clinical and surgical setting, the evidence for making critical diagnostic and therapeutic decisions based on results obtained from these assays is still largely premature; caution should be exercised.

BLEEDING IN THE CRITICALLY ILL CHILD

It is not uncommon for the general pediatric hematologist to be consulted in the critical care setting for acute bleeding in the presence of abnormally prolonged clotting tests, thrombocytopenia, or suspected platelet dysfunction. Several clinical situations may lead to the presence of acquired bleeding in the inpatient setting; when the underlying cause is resolved, bleeding typically stops (Table 29-3). Perhaps the most common consult for excessive bleeding in this setting concerns consumption of clotting factors and platelets in the presence of DIC.

TABLE 29-3 Acquired Bleeding Disorders

Underlying Bleeding Disorder	Hemostatic Defect	Cause
Overwhelming sepsis	Acute DIC	Initiation of coagulation, damage to the endothelium; decrease in clotting and anticlotting factors
Liver disease	Multiple coagulation factor deficiency	Decreased hepatic synthesis Increased fibrinolysis Decreased clearance of plasminogen activators Hypercoagulable state Decreased production of natural anticoagulants Thrombocytopenia Hypersplenism
Malabsorption syndrome	Decreased production of factors II, VII, IX, and X and proteins C and S	Vitamin K deficiency
Cyanotic congenital heart disease	Mild to moderate thrombocytopenia	Shortened platelet survival Abnormal platelet function Acquired defects in platelet aggregation
Acyanotic congenital heart disease (e.g., ASD, PDA)	Decreased high-molecular-weight VWF multimers	Consumption
ECMO and CPB platelet dysfunction	Platelet activation in the oxygenator and physical damage to the platelet membrane	Coagulation factor deficiency Consumption of coagulation factors in the circuit Hyperfibrinolysis Increase in tPA and decrease in α_2-antiplasmin
Acute promyelocytic leukemia	Thrombocytopenia Decreased production in bone marrow and increased consumption	Disseminated intravascular coagulation Release of procoagulant material from the leukemic cells Hyperfibrinolysis Increased synthesis of plasminogen activators

ASD, Atrial septal defect; *CPB,* cardiopulmonary bypass; *ECMO,* extracorporeal membrane oxygenation; *PDA,* patent ductus arteriosus; *tPA,* tissue plasminogen activator; *VWF,* von Willebrand factor.

Box 29-1 **Conditions Associated with Disseminated Intravascular Coagulation**

- Sepsis (particularly gram-negative bacteremia)
- Trauma
  - Massive tissue injury
  - Head injury
- Fat embolism
- Malignancy
  - Acute promyelocytic leukemia
  - Myeloproliferative disorders
- Obstetric accidents
- Vascular disorders
  - Giant hemangiomas (Kasabach-Merritt syndrome)
  - Aortic aneurysm
- Toxins
  - Snake venom
  - Drug overdose
- Immunologic reactions
  - Severe anaphylaxis
  - Acute hemolysis
  - Acute transplant rejection

DIC is an acquired systemic disorder characterized by widespread activation of coagulation and deposition of fibrin leading to the formation of thrombi in the microcirculation accompanied by secondary activation of fibrinolyis.[72] DIC can be acute or chronic, compensated or decompensated, and caused by a wide variety of conditions (Box 29-1). DIC should be suspected in children with shock and bleeding manifestations. In DIC the PT and APTT are usually both prolonged, with decreased fibrinogen, factor VIII, and factor V. A concomitant decrease in natural anticoagulants (protein C, protein S, and antithrombin III) may also be seen. Examination of the peripheral smear usually reveals the presence of schistocytes and thrombocytopenia.[93] There is also an increase in D-dimer and FDPs secondary to the formation of plasmin. As discussed earlier in the chapter, in most cases the diagnosis of the cause of bleeding becomes complicated by the need for immediate therapeutic intervention, which usually requires replacement products.

CHAPTER 30

Inherited Platelet Disorders

Michele P. Lambert and **Mortimer Poncz**

CHAPTER OUTLINE

QUALITATIVE DISORDERS
Platelet Membrane
Glanzmann Thrombasthenia: Defective Platelet Integrin $\alpha_{IIb}\beta_3$
Other Integrins in Inherited Platelet Disorders
Bernard-Soulier Syndrome: Defective Glycoprotein Ib/IX Complex
Platelet-Type von Willebrand Disease (Pseudo–von Willibrand Disease)
Other Inherited Defects of Platelet Receptors
Defects in Signal Transduction
Platelet Storage Granule Defects
QUANTITATIVE DISORDERS
Disorders of Platelet Production

Platelets are small (1 to 4 µm in diameter) and were once thought to be fragments of other mature blood cells, dismissed as "blood dust." They are now known to be highly specialized and organized structures released (by a still partly understood process called *thrombopoiesis*) from megakaryocytes. Platelets are a critical component for the first phase of hemostasis (formation of the platelet plug), which can halt the loss of blood from vessels whose endothelial integrity has been interrupted, though it has become increasingly clear that platelets have important roles in maintaining vascular integrity and the inflammatory response. If platelets are deficient in number or defective in function, excessive bleeding may occur. The clinical manifestations of platelet-type bleeding typically involve the skin or mucous membranes and include petechiae, ecchymosis, epistaxis, menorrhagia, and gastrointestinal hemorrhage (Box 30-1). Intracranial bleeding can occur, but it is infrequent. The deep-muscle hematomas and hemarthrosis typically seen in patients with defects in the fluid-phase (plasma) hemostatic system infrequently occur in platelet disorders.

Inherited platelet disorders can involve a qualitative and/or quantitative defect and are often broadly classified according to one of these two categories. In this chapter, we have classified the platelet disorders by their predominant feature, although many involve combined defects in both platelet number and function. For example, Bernard-Soulier syndrome (BSS) results from defects in the platelet receptor glycoprotein Ibα/Ibβ/IX/V (GPIb/IX) complex, which binds von Willebrand factor (VWF) and is critical for adherence of platelets at sites of vascular injury. This receptor is anchored to the cytoskeleton and is also important in platelet formation from megakaryocytes. Thus many of these patients have macrothrombocytes and low platelet counts, as well as a defect in platelet function. Furthermore, although many inherited platelet disorders have been described, most are extremely rare. Even the well-known disorders such as BSS and Glanzmann thrombasthenia (GT) are uncommon, with a frequency in the general population of 10^{-5} to 10^{-6}, and are mostly seen in inbred populations or consanguineous relationships. In aggregate, however, these inherited disorders are not uncommon and, given the diverse nature of the underlying defects, may pose a significant diagnostic challenge.

QUALITATIVE DISORDERS

Platelet Membrane and Receptors

Sensing abnormalities in their microenvironment, adhering to damaged vascular walls, and aggregating to each other are central functions of circulating platelets. Many of the membrane receptors in these processes have been cloned, and our understanding of the interplay between membrane receptors, intracellular molecules, and the cytoskeleton continues to increase. Initially, these protein receptors were classified by their electrophoretic mobility and molecular mass and numbered sequentially. Now it is clear that many of these proteins are members of several large families of receptors, including the integrin α/β heteroduplexes, the leucine-rich receptors, the G protein–coupled receptors (GPCRs), and the immunoglobulin

superfamily. Such a classification takes advantage of the similar structure and function of members of these families. Frequently, family members share a common family of ligands or activate cells by a common pathway. Table 30-1 lists the members of these families of receptors that are found on platelets, as well as several receptors that do not belong to any of these families. Many of these receptors have other historical names, and these, as well as their cluster differentiation (CD) antigen nomenclature, are noted in the table. Many of the receptors involved in inherited platelet disorders are described in the following text.

Glanzmann Thrombasthenia: Defective Platelet Integrin $\alpha_{IIb}\beta_3$

In 1918, a Swiss pediatrician, Eduard Glanzmann, described a heterogeneous group of disorders that he termed *thrombasthenie* (weak platelets); these disorders were characterized by normal platelet counts but abnormal clot retraction.[1] In 1956 it was noted that these platelets failed to spread onto a surface or to stick to each other (aggregate).[2,3] Glanzmann thrombasthenia (GT; MIM 273800) is now known to be a rare, inherited, autosomal recessive bleeding disorder, the hallmark of which is failure of platelets to bind fibrinogen and aggregate after activation. The underlying defect is an abnormality in the genes encoding either chain of the integrin $\alpha_{IIb}\beta_3$ fibrinogen receptor (see Table 30-1). GT is the most common of the inherited platelet disorders associated with a severe bleeding phenotype.[4]

Biology of the $\alpha_{IIb}\beta_3$ Receptor

The α_{IIb} and β_3 subunits are encoded by separate genes (*ITGA2B* and *ITGB3*) that are closely linked on chromosome 17q21-23.[5] α_{IIb} is approximately 145 kD in size and contains 18 cysteine residues arranged into 9 disulfide bonds that are rather evenly spaced throughout its length (Fig. 30-1). The α_{IIb} prochain complexes with the β_3 subunit in the endoplasmic reticulum. During maturation in the Golgi body, the α_{IIb} prochain is cleaved into the α_{IIb} heavy fragment and the α_{IIb} light fragment, with the two fragments remaining linked by a disulfide bond. Like many other integrin α chains, α_{IIb} contains four calcium-binding domains near its N-terminal. This region in all α

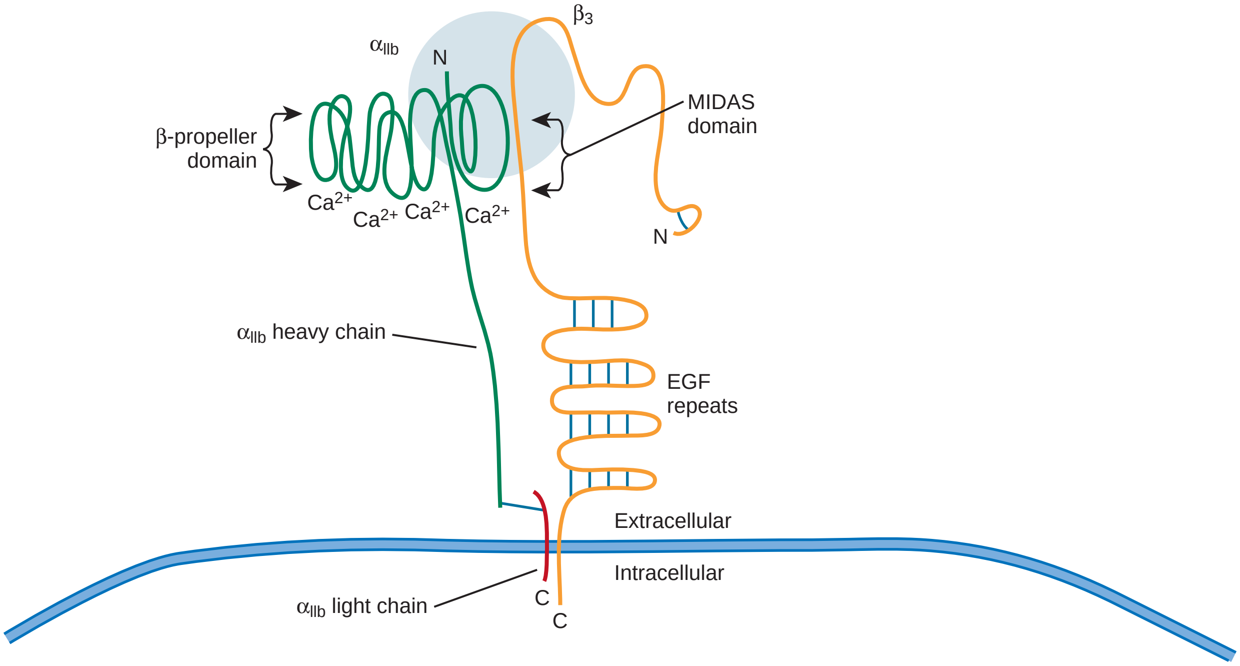

Figure 30-1 Structure of the $\alpha_{IIb}\beta_3$ receptor. Both units of the $\alpha_{IIb}\beta_3$ heteroduplex contain a transmembrane domain with short intracellular tails. The α_{IIb} extracellular domain is cleaved into two parts: the α_{IIb} heavy chain, which has the N-terminal β-propeller domain, and the α_{IIb} light chain, which spans the space from the extracellular compartment to the intracellular compartment. The β_3 chain contains multiple cysteine disulfide bonds represented by the *gray lines*. The MIDAS (metal ion–dependent adhesion site) domain is indicated. The pocket on $\alpha_{IIb}\beta_3$ that may represent the ligand-binding domain is shown as a *gray ball*. *EGF*, epidermal growth factor.

subunits contains seven homologous repeats that fold into a β-propeller structure[6]; portions of the surface loops of this structure are critical for ligand binding (in interaction with the βA domain of the β_3 subunit).[7]

Similar to other integrin β chains, β_3 is approximately 90 kD and contains 762 amino acid residues in its mature form (see Fig. 30-1).[7] β_3 contains five cysteine-rich regions for a total of 56 cysteine residues, including a large disulfide-bonded loop, termed the βA region, that extends from amino acids Cys5 to Cys435.[6] This loop participates in fibrinogen binding and contains three divalent cation-binding domains that appear to be important in ligand binding. One of these cation-binding sites (the βA MIDAS–metal ion–dependent adhesion site) interacts directly with ligand, and binding of cations to the βA domain may stabilize the ligand-occupied conformation.

There are about 8×10^4 $\alpha_{IIb}\beta_3$ receptors per platelet, making this receptor the most abundant one on platelets (see Table 30-1).[8] Most of these receptors are located on the platelet surface, although a portion are found on the inner surface of alpha granules and are involved in the localization of fibrinogen to these granules.[9] On resting platelets, $\alpha_{IIb}\beta_3$ exists in a folded, inactive state that does not interact with its ligand. However, upon platelet activation, an “inside-out” signaling event takes place in which the $\alpha_{IIb}\beta_3$ complex is activated and unfolded like a switch blade,[7] thereby resulting in binding of fibrinogen at the N-terminals of the two proteins and platelet aggregation. After ligand binding, an “outside-in” signal mediates integrin-cytoskeleton interactions and platelet spreading.[10]

Many integrin ligands contain an arginine-glycine–aspartic acid (RGD) motif that participates in integrin binding. Conversely, peptides containing RGD act as competitive inhibitors of ligand binding.[11] For example, the RGD motif located in the C1 domain of VWF appears to be necessary for binding of VWF to $\alpha_{IIb}\beta_3$. In contrast, deletion of the two RGD sequences in the fibrinogen α chain does not impair its ability to bind to $\alpha_{IIb}\beta_3$. Rather, binding of fibrinogen to $\alpha_{IIb}\beta_3$ requires a KQAGD sequence located at the carboxyl-terminal of the fibrinogen γ chain.[12]

Whereas expression of the α_{IIb} chain is restricted to megakaryocytes, the β_3 subunit is expressed more widely as a component of the $\alpha_V\beta_3$ (vitronectin) receptor. Mouse studies have shown that deletion of $\alpha_V\beta_3$ function results in placental defects and osteosclerosis,[13] although to date no differences have been noted between patients with GT caused by an α_{IIb} or β_3 defect.[4]

Clinical Features

Thrombasthenia is characterized by repeated mucocutaneous bleeding beginning at an early age (Fig. 30-2, *A*). Epistaxis and gastrointestinal bleeding are frequent issues in early childhood that often require intervention, as well as early iron supplementation. Menorrhagia is a critical problem in teenage girls.[14] The bleeding that normally accompanies pregnancy, surgical procedures, tooth extraction, or physical trauma can be excessive in GT patients. Unprovoked intracranial or gastrointestinal hemorrhage occurs and accounts for a significant portion of the observed 5% to 10% premature mortality

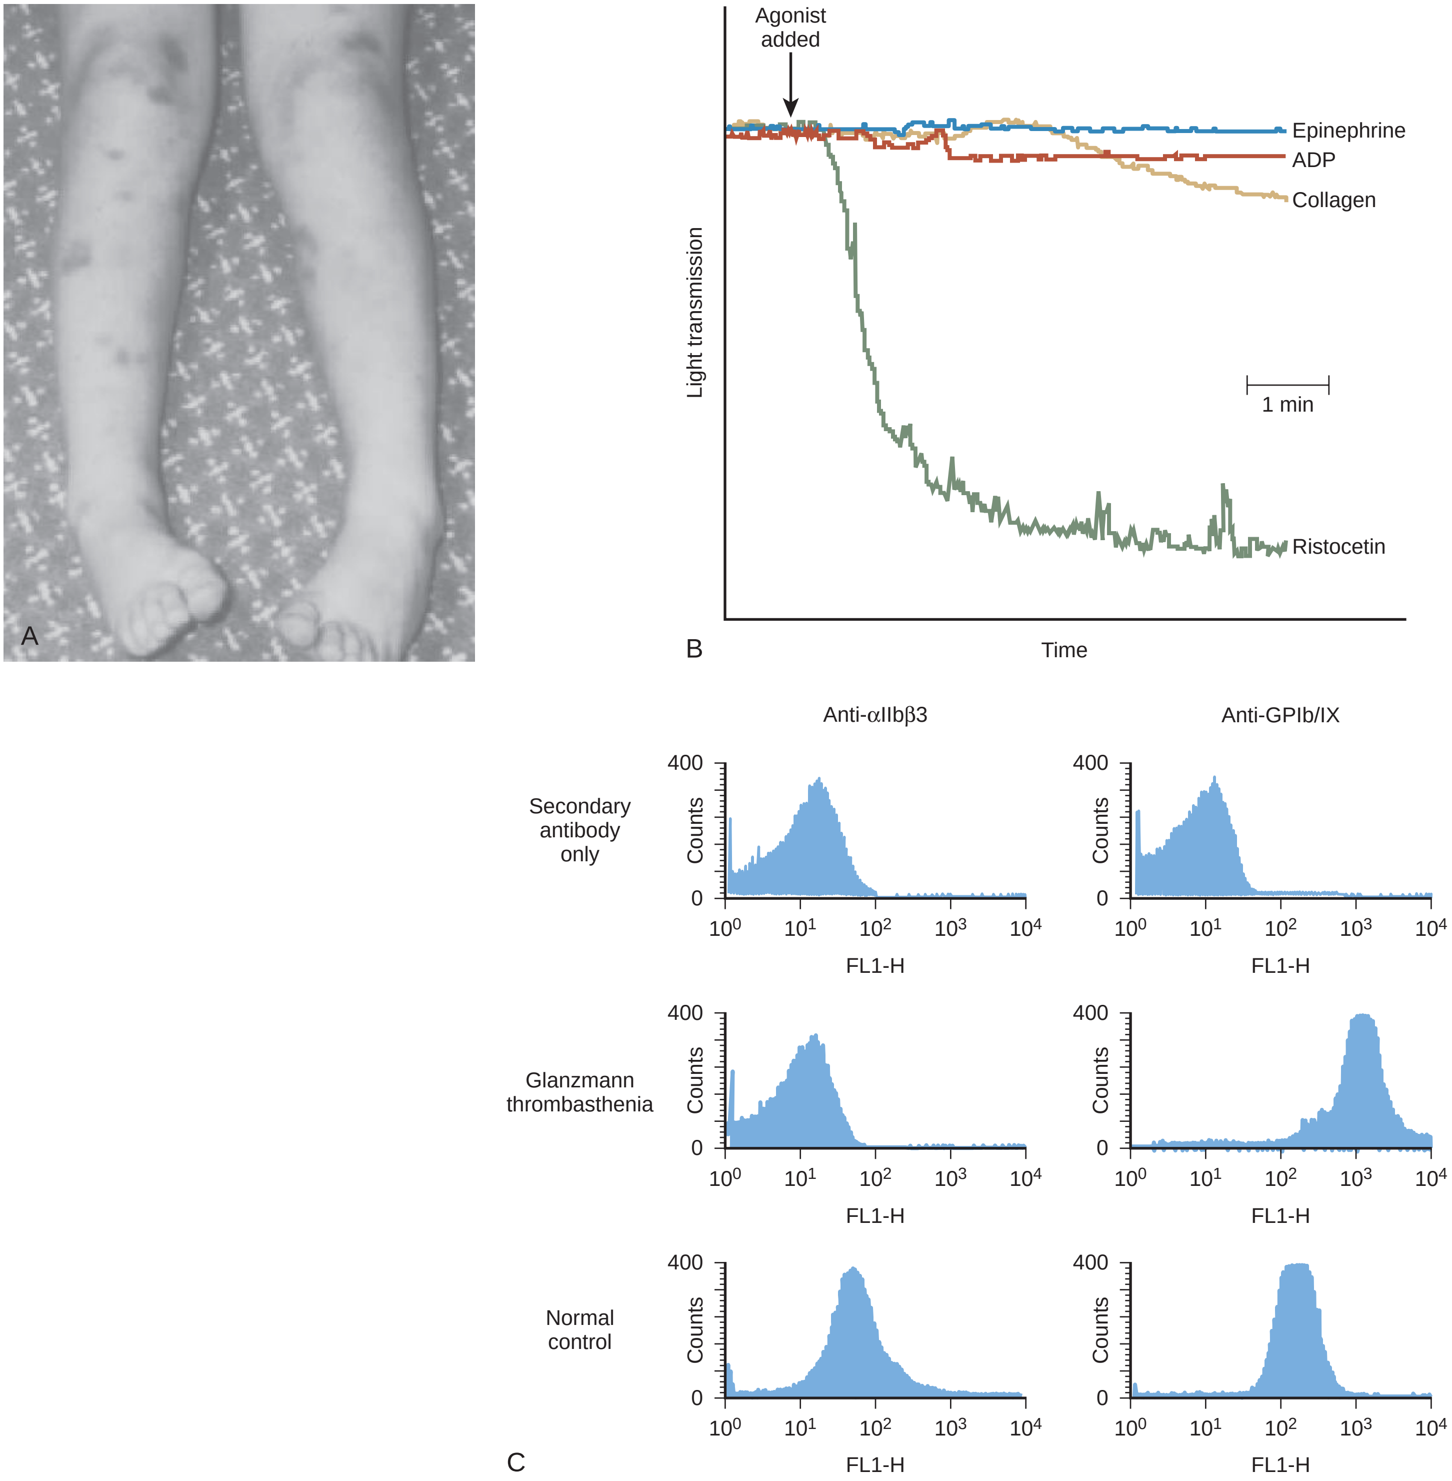

Figure 30-2 Glanzmann thrombasthenia. The patient shown has a mutation in the fourth cysteine-binding domain of α_{IIb} secondary to a Gly273Asp substitution.[183] **A**, Representative ecchymosis seen in the patient at the age of 6 years. **B**, Platelet aggregation studies show an absence of secondary aggregation to adenosine diphosphate (ADP), epinephrine, and collagen but a normal response to ristocetin. **C**, Flow cytometric platelet analysis using an anti-$\alpha_{IIb}\beta_3$ primary antibody (*left*) or an anti-GPIb/IX antibody as a positive control (*right*), followed by a fluorescein isothiocyanate–labeled secondary antibody. Shown at the *top* is the fluorescence with the secondary antibody only on normal platelets. In the *middle* is a Glanzmann thrombasthenia patient with primary antibody followed by secondary antibody, and at the *bottom* is the same with normal platelets. The patient's platelets show little $\alpha_{IIb}\beta_3$ antibody binding when compared with the control. The patient's platelets do express high levels of glycoprotein Ib/IX (GPIb/IX).

rate. In addition, some patients experience joint bleeding or muscle hematomas more characteristic of the hemophilias.[14]

Most frequent is recurrent and problematic epistaxis often complicated by prior nasal cauterizations that damage the local nasal architecture. Frequently, local compression strategies or topical applications of thrombin are useful when bleeding occurs. DDAVP (1-deamino-8-δ-arginine vasopressin) has been used as well, and oral contraceptive management of menorrhagia is generally sufficient. Platelet transfusions may be useful until resistance to platelet infusions develops, although patients do not necessarily form antibodies to the $\alpha_{IIb}\beta_3$ receptor. Antibodies may be particularly problematic because they may not only result in increased platelet clearance or platelet refractoriness but may also interfere with platelet function.[15] Case reports and small case series suggest that recombinant activated factor VII may be a useful supplement to platelet transfusions.[16,17] We have also successfully used embolization of arterioles feeding the nose and uterus in cases of recurrent, life-threatening hemorrhage.

Incidence

Although infrequent worldwide, GT is more prevalent among certain isolated populations and in the setting of consanguineous relationships, particularly among Arab populations,[17] Iraqi Jews,[18] French gypsies,[19] and individuals from southern India.[20] Heterozygotes for this disease have approximately 50% of the normal number of $\alpha_{IIb}\beta_3$ receptors, but generally no evidence of platelet dysfunction or clinically significant bleeding.[14] Although most cases are observed in specific populations or in the setting of consanguinity and are thus homozygous for a shared mutation inherited from both parents, about one third of patients with identified mutations are compound heterozygotes.[4]

Classification and Laboratory Diagnosis

In 1972, Jacques Caen classified GT according to platelet intracellular fibrinogen content and the ability of platelets to retract a fibrin clot.[21] Type I patients, representing 80% of those studied, lacked platelet fibrinogen and had an absence of clot retraction. Type II thrombasthenic platelets contained appreciable levels of platelet fibrinogen and maintained some clot retraction capability. Soon thereafter, the technique of sodium dodecyl sulfate–polyacrylamide gel electrophoresis became widespread, and it became clear that there were three different patterns seen with thrombasthenic platelet membrane glycoproteins.[4] Type I platelets lacked detectable levels of $\alpha_{IIb}\beta_3$, whereas type II platelets expressed moderate (15% to 25%) levels of these glycoproteins. Adding to the complexity of this classification was the identification of variant forms of thrombasthenia characterized by normal to nearly normal levels of a dysfunctional form of $\alpha_{IIb}\beta_3$ (type III).[4] Finally, a related integrin dysfunction syndrome was identified involving a GT-like platelet defect along with a white cell disorder termed *leukocyte adhesion deficiency type III*.[22] These patients have a deficiency of Kindlin-3 (encoded by the *FERMT3* gene on chromosome 11), an intracytoplasmic signaling molecule involved in the function of β_2- as well as β_3-based integrins. Patients have both GT-like bleeding manifestations and the infectious complications and leukocytosis of leukocyte adhesion deficiency.[15]

GT patients fail to aggregate in response to physiologic agonists such as adenosine diphosphate (ADP), thrombin, or epinephrine (see Fig. 30-2, *B*) because they all have a functional deficiency of platelet surface $\alpha_{IIb}\beta_3$ receptors. The failure to bind fibrinogen and other adhesive ligands is the reason for the inability of platelets to aggregate. No correlation exists between any of the proposed subtypes of GT and the severity of bleeding symptoms in patients.[4] Some patients with no $\alpha_{IIb}\beta_3$ have relatively mild clinical symptoms, whereas others with a full complement of $\alpha_{IIb}\beta_3$, albeit dysfunctional, can have frequent bleeding episodes requiring repeated transfusions.

Currently, the most common method used for determining levels of $\alpha_{IIb}\beta_3$ on thrombasthenic platelets involves flow cytometry and immunoblot analysis.[4] Figure 30-2, *C* illustrates flow cytometric analysis of the $\alpha_{IIb}\beta_3$ content of both a normal control and a GT patient with a severe deficiency of $\alpha_{IIb}\beta_3$ secondary to a mutation in one of the Ca^{2+}-binding domains of her α_{IIb} chain.[23] This mutation blocks export of the $\alpha_{IIb}\beta_3$ receptor out of the endoplasmic reticulum and into the Golgi body for final processing, as indicated by failure to cleave the α_{IIb} prochain into an α_{IIb} heavy chain.

Several hundred individuals with GT have been described in the literature. To date, more than four hundred different mutations have been described. As in most genetic disorders, the molecular abnormalities have been found to range from major deletions and inversions to single point mutations.[4,23a] Some of the better-characterized subgroups of mutations are described in the following text.

The earliest and largest group of thrombasthenic mutations described failed to express $\alpha_{IIb}\beta_3$ on the cell surface. Several of these patients had major deletions or inversions in their α_{IIb} or β_3 genes. In addition, a number of point mutations or small deletions in the α_{IIb} or β_3 genes have been described with no surface expression of $\alpha_{IIb}\beta_3$; both chains are formed intracellularly and may assemble the complex but fail to undergo intracellular processing or reach the cell surface. These defects result in the type 1 form of thrombasthenia. One major subgroup of these patients involves missense mutations in the N-terminal β-propeller repeats of α_{IIb} near the proposed Ca^{2+}-binding sites on its lower surface as exemplified by the patient in Figure 30-2.[23,24]

Another group of mutations occur in the same β-propeller region of α_{IIb} but take place on the upper surface and have expressed surface receptor that cannot bind its ligand. These mutations are located within three upper loops of the β-propeller, the connecting loop between the second and third blades, the loop in the middle of the third blade, and the loop connecting the third and fourth blades.[25] These mutations occur within the pocket of α_{IIb} that binds RGD ligand.[6]

Other thrombasthenic patients with significant levels of nonfunctional $\alpha_{IIb}\beta_3$ surface expression have mutations that involve the β_3 chain. These mutations result in a surface $\alpha_{IIb}\beta_3$ that is easily dissociable by chelation of external calcium ions.[26] Many of these missense mutations have been identified within the cation-binding MIDAS domain.[6] The importance of these sites was reinforced by the identification of a group of in vitro–generated mutant $\alpha_{IIb}\beta_3$ receptors expressed in Chinese hamster ovary cells, which provided independent support for the importance of the MIDAS domain in ligand binding.[27]

A second group of dysfunctional mutations with normal levels of surface $\alpha_{IIb}\beta_3$ receptors are localized to the cytoplasmic domain of β_3, thus demonstrating the importance of this domain for integrin activation and regulation of ligand binding.[4] These mutations do not affect surface expression of platelet $\alpha_{IIb}\beta_3$ complexes, but mutant receptors are unresponsive to agonist stimulation. These mutations provide compelling evidence for the role of the β_3 cytoplasmic tail in downstream platelet activation by $\alpha_{IIb}\beta_3$.

Other Integrins in Inherited Platelet Disorders

Other integrins that are infrequently associated with platelet dysfunction include the $\alpha_2\beta_1$ (glycoprotein Ia/IIa) receptor, an Mg^{2+}-dependent collagen receptor on many cells, including platelets.[28] In platelets, collagen not only serves as an adhesive substrate but it also functions as an agonist for platelet aggregation. Patients with histories of bleeding have been reported whose platelets failed to respond normally to collagen and lacked $\alpha_2\beta_1$, thus suggesting that binding of collagen to $\alpha_2\beta_1$ is a necessary component for collagen-induced signaling.[29] In addition, another report described several families with autosomal dominant thrombocytopenia and mild platelet dysfunction associated with mutations in the α_2 subunit.[30]

There is substantial variability in the density of $\alpha_2\beta_1$ on the surface of platelets from different individuals.[31] These differences in $\alpha_2\beta_1$ expression are associated with the inheritance of three different α_2 alleles. The higher the receptor density, the greater the attachment of platelets to type I collagen. Some, but not all, epidemiologic surveys suggest that increased $\alpha_2\beta_1$ density is a risk factor for cardiovascular disease.[32] An increased prevalence of the allele with lower $\alpha_2\beta_1$ density has been reported in patients with type 1 von Willebrand disease (VWD), which suggests that this allele may contribute to bleeding symptoms in these patients.[33]

Bernard-Soulier Syndrome: Defective Glycoprotein Ib/IX Complex

Bernard-Soulier syndrome (BSS: MIM 231200) was first described in 1948 in a 5-month-old infant with a prolonged bleeding time and giant platelets on blood smear and who had had a sibling who died of hemorrhage.[34] Over the following years, additional patients with the combination of mucocutaneous bleeding; enlarged platelets; normal platelet aggregation with ADP, collagen, and epinephrine with a delayed response to thrombin; and absent platelet aggregation with human VWF and ristocetin or with bovine VWF alone were described as having BSS, now the second most recognized inherited severe platelet disorder.

Biology of the Glycoprotein Ib/IX Complex

Adhesion through the GPIb/IX complex involves binding of VWF to the subendothelium. Platelet membranes contain two binding sites for VWF (see Table 30-1). One of these sites requires previous platelet activation and is located on the platelet membrane $\alpha_{IIb}\beta_3$ complex. The second binding site involves the GPIb/IX complex, and it is this membrane complex that is crucial for initial attachment and proper adhesion to the extracellular matrix of a damaged vessel wall. It should be pointed out that the GPIb/IX complex may also bind to other ligands, including P-selectin, thrombospondin-1, high-molecular-weight kininogen, and Mac-1.[35] Furthermore, GPIb/IX also binds thrombin, and its role in the activation of platelets by thrombin is discussed later.

The GPIb/IX complex is the second most abundant receptor on the platelet membrane surface, with approximately 25,000 copies per platelet.[36] This complex actually consists of four different proteins (Fig. 30-3), all of which have one or more leucine-rich repeats composed of a 24–amino acid motif with 7 conserved leucine residues. Other proteins have been described with this leucine-rich repeat, and these regions mediate ligand binding.[37]

GPIbα is the largest subunit (135 kD, 610 amino acids, chromosome 17p12) and has 7 leucine repeats. It is susceptible to cleavage by trypsin or calpain, which gives rise to a heavily glycosylated 135-kD fragment known as *glycocalicin*. In addition to containing the binding site for VWF, the glycocalicin portion of GPIbα also binds thrombin. Under normal flow in vivo, plasma VWF does not bind to the GPIb complex, but under shear stress conditions, VWF simultaneously binds to collagen and the GPIb/IX complex.[38] In clinical assays, the antibiotic ristocetin or the venom-derived protein botrocetin is used to mimic this effect by inducing conformational changes in VWF that promote binding to GPIb/IX in stirred platelet-rich plasma.[39]

GPIbα is disulfide-bonded to GPIbβ (25 kD, 181 amino acids, chromosome 22q11.2) through a single cysteine residue located in each subunit near the transmembrane domains of GPIbα and GPIbβ (see Fig. 30-3). This peptide has only one leucine repeat. The cytoplasmic tail of GPIbβ contains a filamin-binding site that links the receptor complex to F-actin below the membrane and a binding site for 14-3-3ζ. The disulfide-bound GPIbα-β is noncovalently associated with platelet GPIX and GPV. GPIX is the smallest member of the GPIb complex (22 kD, 160 amino acids, chromosome 3q29), with only one leucine repeat.[38] GPV (82 kD, 344 amino acids, chromosome 3q21) is a transmembrane protein with 15 leucine repeats.[40] This protein is a proteolytic substrate for thrombin and releases a 69-kD soluble fragment. GPV is present in only a single copy per complex, whereas there are two copies of the other three subunits in a single receptor (see Fig. 30-3). Furthermore, cleavage of the GPV extracellular domain by thrombin bound to GPIbα activates platelets.[41] Consistent with this observation, the GPV-knockout mouse has a mild prothrombotic state.[42]

Binding of activated VWF to the GPIb/IX complex activates platelets through activation of phospholipase C

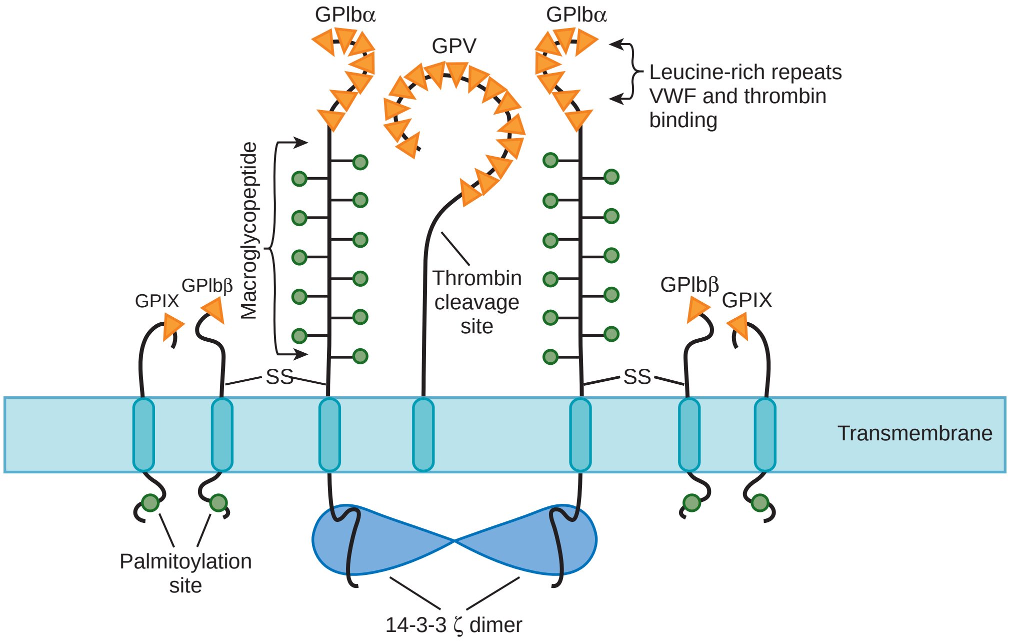

Figure 30-3 Structure of the glycoprotein Ib/IX (GPIb/IX) receptor. Each receptor consists of two GPIbα chains, each disulfide linked to a GPIbβ chain. There are two GPIX chains and one GPV chain in each complex as well. The leucine-rich repeats on all the chains are indicated, as are the sites for binding of von Willebrand factor (VWF) and thrombin. Known intracellular interactions or modification sites are also indicated. *SS*, cysteine disulfide bond.

(PLC) and mobilization of protein kinase C, which, together with increases in $[Ca^{2+}]_i$, promotes platelet secretion and potentiates platelet aggregation. The GPIb-IX complex also appears to activate the cell by binding to the cytoskeleton protein 14-3-3ζ and by interacting with the FcγRIIA receptor on platelets, where it activates an intracellular tyrosine–based activation motif receptor (see Fig. 30-3).[43]

Clinical Features

The bleeding manifestations of patients with BSS are similar to those of other patients with severe platelet dysfunction and center on mucocutaneous bleeding with purpura, epistaxis, gastrointestinal hemorrhage, and menorrhagia.[44] Alloantibodies to components of the GPIb/IX complex can develop after platelet transfusions with resulting platelet refractoriness.[44] Care of bleeding in these patients is similar to that of patients with GT discussed earlier, including the use of DDAVP.[45] Studies evaluating DDAVP have demonstrated improved bleeding times, although the improvement did not correlate with the ability of DDAVP to increase the level of circulating VWF. Recombinant activated factor VII has also been reported to be useful in patients with BSS,[46] but data are still very limited and it is probably most effective in combination with platelet transfusion.

Classification and Laboratory Diagnosis

BSS patients have a variable degree of thrombocytopenia. Most patients are thrombocytopenic to some extent, but some patients may have platelet counts as low as 20,000/µL. However, care must be taken to avoid underestimation of platelet number due to the macrothrombocytopenia.[47] The platelets have a mean diameter ranging from 3 to 20 times normal (Figs. 30-4, *B* and 30-5, *A*). Other cell types appear normal. In general, the circulating total platelet mass in people is more precisely conserved than the platelet count is, and part of the decrease in platelet count in BSS may well reflect this compensatory mechanism. Megakaryocytes in this disorder appear normal in size and appearance by light microscopy. However, on electron microscopy, a striking feature in these cells is the variable and intermittent nature of the demarcation system, which is often vacuolar.[48] Absence of GPIbα results in an abnormal demarcation membrane in a mouse model of BSS.[49] Studies have shown that GPIb/IX contributes to platelet formation in that this complex lines up with the cytoskeleton during thrombopoiesis and plays a role in cell cycle regulation.[50]

Bleeding times and platelet functional analyzer–100 measurements are prolonged in these patients,[51] but the distinctive abnormality of BSS platelets is the failure of agglutination in the presence of ristocetin, an abnormality that cannot be corrected by the addition of normal plasma. Aggregation by other agonists such as ADP, collagen, and epinephrine is normal, although the response to low-dose thrombin may be delayed.[52] Flow cytometric analysis of platelet glycoproteins shows decreased surface expression of the GPIb/IX complex and may aid in the diagnosis.[53]

Molecular Abnormalities

Molecularly, there appear to be two forms of BSS. In the biallelic form, most often homozygous mutations result in severely reduced or absent GPIb/IX expression. Heterozygous family members are usually asymptomatic with normal platelet counts. For the biallelic form, more than 50 mutations of the *GP1BA, GPIBB,* and *GP9*

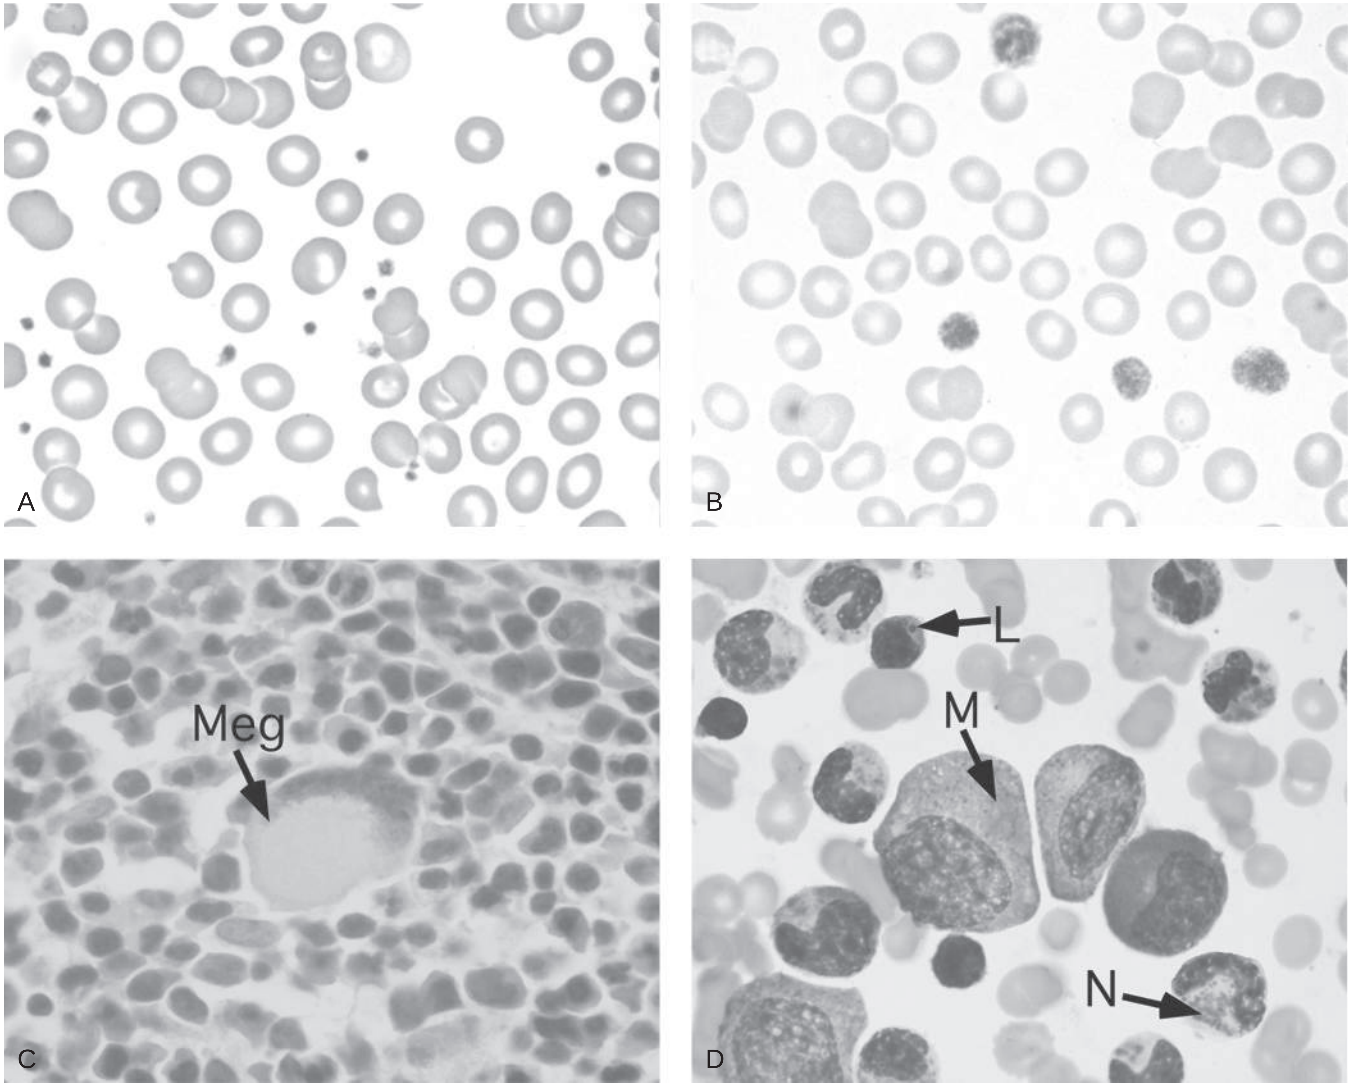

Figure 30-4 Light microscopy. **A**, Normal peripheral smear showing platelets of typical size (original magnification ×100). **B**, Peripheral smear of a patient with Bernard-Soulier syndrome showing a decreased number of enlarged platelets (original magnification ×100). **C**, Dysmorphic megakaryocyte (Meg) with the nuclei pushed to the side in a patient with a GATA1 mutation (original magnification ×50). **D**, Bone marrow in a patient with Chédiak-Higashi syndrome showing inclusion bodies in a myelocyte (M), neutrophil (N), and lymphocyte (L) (original magnification ×100). *(Courtesy of Marybeth Helfrich, The Children's Hospital of Philadelphia.)*

genes have been defined.[54] Few patients are compound heterozygotes, suggesting that this is a rare disease outside of specific populations. Most of the mutations described are missense or nonsense mutations. Deletions are uncommon but do occur, as in one patient who had partial deletion of the *GPIBB* gene on chromosome 22q11.2 in association with velocardiofacial syndrome.[55] In the monoallelic form, the platelet count is usually somewhat decreased and the bleeding tendency is often less dramatic. However, in some families,[54] there is significant thrombocytopenia and severe bleeding, in particular with the p.Ala156Val mutation in Italy, and three other missense mutations (p.Asn57His, p.Tyr70Asp, and p.Leu73Phe) in *GP1BA*. These mutations are associated with decreased expression of the GPIb/IX complex and macrothrombocytopenia. It is not clear why some mutations appear to exhibit a dominant negative effect so that heterozygous patients manifest disease whereas other heterozygous patients are asymptomatic. Indeed, patients with 22q deletion syndrome (22qDS, velocardiofacial syndrome, DiGeorge syndrome) often have deletion of one copy of *GP1BB* but may only manifest mild macrothrombocytopenia with decreased expression of the GPIb/IX complex.

Platelet-Type von Willebrand Disease (Pseudo–von Willibrand Disease)

Platelet-type von Willebrand disease (VWD), also known as *pseudo–von WIllibrand disease*, is an autosomal dominant bleeding disorder often associated with a prolonged bleeding time, mild thrombocytopenia, and decreased circulating levels of high-molecular-weight VWF multimers.[56,57] Patients with this disorder have a mild to moderate bleeding diathesis. Platelet-type VWD is very similar to type 2B VWD (see Chapter 31) in that both are characterized by platelet agglutination in the presence of low

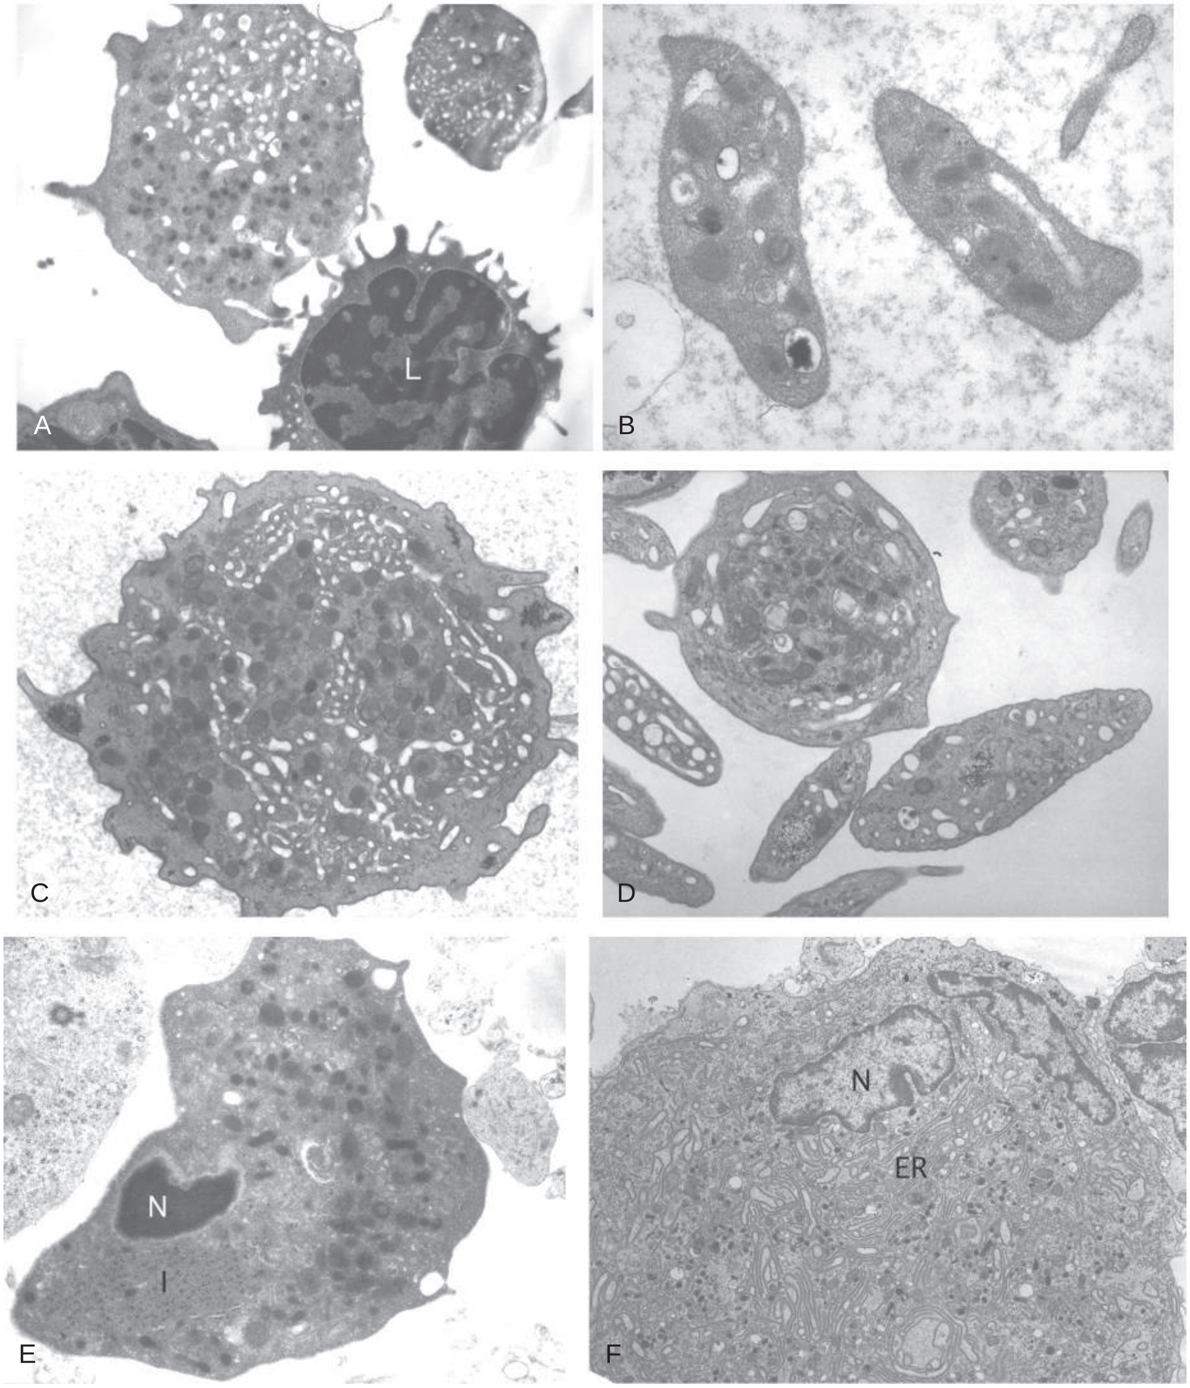

Figure 30-5 Electron microscopy. **A**, Platelet in a patient with Bernard-Soulier syndrome that is as large as a lymphocyte (L). Otherwise, platelet morphology is normal (original magnification ×18,000). **B**, Platelets in patients with Wiskott-Aldrich syndrome are half to two thirds the normal size but otherwise normal in appearance (original magnification ×38,500). **C**, Platelets in patients with Fechtner syndrome are enlarged and the canalicular system is exuberant, but otherwise the platelets look normal (original magnification ×13,000). **D**, Platelets in patients with gray platelet syndrome vary in granule content. Most of the platelets seen have an absence of alpha granules, whereas others (such as the large platelet here) may have identifiable granules (original magnification ×16,500). **E**, Neutrophil in a patient with myosin heavy–chain 9–related disorder showing an inclusion body *(I)* below the nucleus *(N)* forming longitudinally oriented filaments (original magnification ×14,000). **F**, Megakaryocyte from a patient with a GATA1 mutation showing the nucleus *(N)* pushed to the side by exuberant endoplasmic reticulum *(ER),* which fills most of the cytoplasm (original magnification ×38,000*). (All electron micrographs courtesy of Dr. James White, University of Minnesota.)*

concentrations of ristocetin and by decreased circulating levels of high-molecular-weight VWF multimers. Binding of VWF to circulating platelets results in the reduced levels of VWF seen in these patients, as well as some degree of platelet activation, mild or intermittent thrombocytopenia, and an increased risk of clotting.

Unlike type 2B VWD, where mutations in *VWF* result in increased affinity for a normal platelet GPIb/IX complex, pseudo-VWD is caused by an alteration in the platelet GPIb/IX complex that leads to increased affinity for normal VWF multimers. Platelet-type VWD can be distinguished from type 2B VWD by the addition of normal VWF to patient platelet-rich plasma, which results in spontaneous aggregation of pseudo-VWD platelets but not type 2B VWD platelets.[57] It is important to distinguish patients with platelet-type VWD from other VWD patients because care of patients with VWD often involves infusion of VWF that contains factor VIII concentrates or DDAVP. This therapy can worsen the thrombocytopenia in patients with platelet-type VWD.[57] A patient with mild thrombocytopenia and a prolonged bleeding time should be evaluated for this disorder.

The molecular basis of platelet-type VWD has been defined in multiple families.[57] Mutations, such as Gly233Val and Met239Val, occur in the region of *GP1BA* that has been previously shown to be important in VWF binding. It has been hypothesized that these mutations alter GPIbα such that it maintains an adhesive conformation much as wild-type GPIb/IX receptor becomes activated on exposure to components of the extracellular matrix at sites of vascular injury and flow.

Montreal platelet syndrome, characterized by macrothrombocytes, a prolonged bleeding time, spontaneous aggregation of platelets at pH 7.4, and a defect in platelet calpain metabolism, was thought to be a distinct macrothrombocytopenia, but in 2009 was shown to be a particular subtype of type 2B VWD, with a V1316M mutation in *VWF*.[58] This disorder demonstrates the overlap between the described phenotypes in these inherited platelet disorders and the value of molecular diagnosis.

Other Inherited Defects of Platelet Receptors

G Protein–Coupled Receptors

Many agonists that activate platelets, such as thrombin, ADP, and thromboxane A_2 (TxA_2), activate cells through a G protein–coupled receptor (GPCR) (see Table 30-1). These seven-transmembrane receptors are linked to a heterotriplex of intracellular guanosine diphosphate (GDP)/guanosine triphosphate (GTP)–binding proteins, Gα, β, and γ. The strongest platelet agonist is thrombin. As mentioned previously, one receptor for thrombin is the GPIb/IX complex. However, thrombin appears to have its greatest effect on human platelets through two GPCRs, protease-activated receptor 1 (PAR-1) and PAR-4, with PAR-1 being the major human receptor.[59] Thrombin binds to PAR-1, releases an N-terminal peptide, and leaves a new N-terminus. An oligopeptide of this N-terminal sequence, SFLLRN, can mimic the effects of thrombin and activate platelets. Surprisingly, no patients with defects in PAR-1 have been described. In mice, PAR-1 is not important for platelet biology, although its absence does have consequences because it is expressed on other tissues.[60] Instead, on murine platelets, PAR-3 and PAR-4 are biologically relevant.[61]

ADP is stored in platelet-dense granules and released upon platelet activation. When added to platelets in vitro, ADP causes TxA_2 formation; protein phosphorylation; and increase in cytosolic Ca^{2+} shape change, aggregation, and secretion. ADP also inhibits the formation of cyclic adenosine monophosphate (cAMP). Several patients with bleeding defects have been described whose platelets showed greatly diminished responsiveness to ADP and reduced numbers of binding sites for ADP analogues,[62,63] a phenotype not dissimilar from that produced by ADP antagonists such as ticlopidine or clopidogrel. ADP receptors on human platelets include P2Y1, P2Y12, and P2X1.[64] P2Y1 is a GPCR that activates PLC. P2Y12 inhibits cAMP formation by adenyl cyclase. P2X1 is a ligand-gated nonspecific cation channel that may contribute to the influx of extracellular Ca^{2+} that occurs in response to ADP. Mutations in each of these receptors have been reported in patients and have resulted in mild to moderate bleeding symptoms.[62]

In several respects, epinephrine is unique among human platelet agonists in that it causes aggregation and secretion but does not cause the cytoskeletal reorganization that underlies shape change. Activation of PLC by epinephrine appears to be dependent on TxA_2 formation and can be suppressed with aspirin. Aspirin also blocks second-wave, or secretion-dependent, platelet aggregation in response to epinephrine. This gives rise to a characteristic aggregometer tracing in which epinephrine-induced primary aggregation is followed by disaggregation of the platelet clumps. Platelet responses to epinephrine are mediated by α_2-adrenergic receptors. There are reports of families in which a mild bleeding disorder was associated with impaired epinephrine-induced aggregation and reduced numbers of α_2-adrenergic receptors.[65] However, platelets from up to 10% of apparently normal people may fail to aggregate when challenged with epinephrine, and the clinical significance of this finding is unclear.

TxA_2 is produced from arachidonate in platelets by the aspirin-sensitive cyclooxygenase pathway. When the stable thromboxane analogue U46619 is added to platelets in vitro, the platelets undergo shape change, aggregation, secretion, phosphoinositide hydrolysis, protein phosphorylation, and an increase in $[Ca^{2+}]_i$. Similar responses are seen when platelets are incubated with exogenous arachidonate. Platelets express a GPCR for TxA_2.[66] Platelets also contain a receptor for prostacyclin (PGI_2), an endothelial cell prostaglandin that is a potent platelet inhibitor. Binding of PGI_2 to this receptor stimulates adenylate cyclase activity and inhibits platelet function.[67] A few patients have been described who have a mild bleeding disorder caused by congenital absence of the TxA_2 receptor. Two Japanese patients have had their mutations defined and were found to have an R60L substitution in the first cytoplasmic loop of *TXA2R*.[68] In addition, three patients have been described who have normal TxA_2 binding but absent platelet aggregation in the presence of this agonist, thus suggesting uncoupling between the receptor and downstream signaling events.[69] There are as yet no known clinical disorders ascribed to the PGI_2 receptor, but deletion of the gene in mice increases their risk for thrombosis after arterial injury[70] and polymorphisms in the PGI_2 gene (*PTGIS*) have been reported to be risk factors for cerebrovascular disease.[71]

Immunoglobulin Superfamily Receptors

GPVI, a 62-kD protein encoded by a gene (*GP6*) on human chromosome 19q13.4,[72] is a member of the immunoglobulin superfamily of receptors and is the platelet-signaling receptor for collagen. Unlike $\alpha_2\beta_1$, GPVI's interaction with collagen initiates intracellular signaling via its surface partner, the FcRγ chain. Signaling occurs via phosphorylation of PLCγ2 and Syk.[73] Fab antibodies derived from GPVI-deficient individuals who had received platelet transfusions recognize GPVI and are capable of blocking activation of platelets by collagen, thereby resulting in thrombocytopenia and internalization and/or cleavage of surface GPVI.[74] Convulxin, a snake venom protein isolated from a South American rattlesnake, is also a potent activator of platelets via GPVI.[75]

GPVI seems to be the major collagen receptor on platelets,[73] although a few patients have been described who lack GPVI and show only a mild bleeding tendency.[76] A mutation in the *GP6* gene has been linked to absence of collagen-induced platelet activation.[77] These patients have some residual platelet aggregation to collagen, which is likely to be through the $\alpha_2\beta_1$ receptor. In addition, autoantibodies to GPVI have been described in patients with immune thrombocytopenic purpura[74] and systemic lupus erythematosus.[78] These patients lack surface GPVI on their platelets and show a mild bleeding diathesis with abnormal platelet aggregation to collagen. Interestingly, several genetic polymorphisms affecting GPVI surface expression have been described and suggested to be a risk factor for myocardial infarction[79] and may be associated with increased risk of pregnancy loss.[80] Platelets with less GPVI showed less vigorous aggregation in vitro, although further study is ongoing on the true relevance of these findings.[81]

Scott Syndrome

The platelet surface functions as one of the principal sites for plasma coagulation reactions by providing a surface on which coagulation factor complexes assemble and accelerate these important reactions several thousandfold. This property of platelet membranes has been termed *platelet factor 3 activity*. In a resting platelet, there is little anionic phospholipid on the platelet's surface. Activation by agonists such as thrombin or collagen is thought to reorient membrane phospholipids and bring anionic phospholipids, chiefly phosphatidylserine, to the outer leaflet. Activation also induces membrane vesiculation and the production of platelet microparticles with procoagulant activity.[82]

Deficiency in platelet coagulant activity is a rare clinical event that has been termed Scott syndrome, named after the propositus of a well-studied family.[83] The patient had prolonged bleeding after dental extractions, bleeding after surgical procedures, and a spontaneous retroperitoneal hematoma. The patient secreted a normal quantity of factor V, a platelet alpha-granule constituent, but had only 25% of the normal number of binding sites for factor Xa on activated platelets. When her platelets were challenged with such agonists as thrombin and collagen, aggregation and secretion were normal but fewer anionic phospholipid-binding sites were translocated to the platelet surface. In addition, the formation of microparticles is defective in patients with Scott syndrome. Standard screening tests for plasma coagulation, such as the prothrombin time and partial thromboplastin time, which use artificial lipid micelles, are normal. Recently, a splice-acceptor site mutation in the gene encoding transmembrane protein 16F (*ANO6*) was reported in the original proband, causing premature termination of a Ca^{2+}-activated chloride channel. Transfection studies provided evidence for the essential role of transmembrane protein 16F in Ca^{2+}-dependent exposure of phosphatidylserine at the platelet surface.[84]

The diagnostic abnormality is a shortened serum prothrombin time as a result of reduced consumption of prothrombin. Additionally, these patients have a prolonged dilute Russell viper venom time that corrects when the patient's plasma is added to normal platelets but not when normal plasma is added to the patient's blood.[85] This is due to the inability to generate normal platelet procoagulant activity. Patients can be readily treated with platelet transfusions, which improve hemostasis and reduce postoperative blood loss.

Defects in Signal Transduction

With multiple overlapping pathways of platelet activation, it has been difficult to define specific defects in patients with inherited disorders of platelet signal transduction. Nonetheless, a small number of patients have been described with phenotypes and abnormal platelet aggregation patterns consistent with such a diagnosis[86]; the number of these patients will likely increase as the diagnostic armamentarium improves because defects in these pathways may be quite common.

Abnormalities of the G proteins (Giα1 and Gαq) have been described in patients with defects in platelet aggregation to ADP and to multiple agonists including ADP, thrombin, and TxA_2, respectively. These patients had lifelong mucocutaneous bleeding associated with these platelet defects.[87] Both of these proteins play an important role in outside-in signaling. Mutations in Gsα (linked to receptors for such agents as PGI_2) have been associated with hypofunction and hyperfunction syndromes. Mutations in prostaglandin E_1 and pituitary adenyl cyclase–activating peptide (PACAP) lead to increased cAMP production, and patients with partial trisomy of 18p have increased PACAP, very increased cAMP, and severe neurologic abnormalities with a pronounced bleeding tendency and mild thrombocytopenia.[88] These patients (signaling defect patients) may be found to have abnormal clot retraction or abnormal spreading of platelets on surface-bound fibrinogen.

Another group of patients lack the ability to liberate arachidonic acid,[89] which may be due to deficiency of phospholipase A_2. Other patients have diminished cyclooxygenase enzyme activity that mimics an aspirin-like defect.[89,90] These patients have abnormal platelet aggregation in response to ADP, epinephrine, collagen, and arachidonic acid but respond normally to prostaglandin G_2, consistent with a defect in cyclooxygenase-1 and subsequent TxA_2 synthesis. Most patients with this disorder have normal antigen levels of a functionally abnormal prostaglandin synthetase. Other patients have been described who have decreased protein expression. Additionally, patients have been reported who have mutations in the gene coding for thromboxane synthetase that converts prostaglandin H_2 to TxA_2.[91]

Finally, pleiotropic aggregation abnormalities due to multiple pathway defects have been associated with mutations in transcription factors. Decreased platelet levels of protein kinase C and PLC-β2 have been found in patients with *RUNX1* mutations (see section on FPD-AML, below), resulting in defects in aggregation and secretion as well as plekstrin phosphorylation in response to thrombin.[91,92] In patients with *GATA1* mutations (see below), abnormal alpha-granule biogenesis, decreased collagen-induced platelet aggregation, and abnormal GPVI-dependent tyrosine phosphorylation have been reported.[93] Over the past few years, other models of platelet dysfunction secondary to a signaling defect have been recognized, including Wiskott-Aldrich syndrome (WAS), which is described later under disorders of platelet size and number. For all these signaling disorders, platelet transfusions are effective in the management of bleeding.

Platelet Storage Granule Defects

Human platelets contain several types of intracellular granules that can be distinguished by electron microscopy, including dense granules, alpha-granules, and lysosomes. Dense granules are the most rapidly secreted granules after platelet activation and contain ADP, adenosine triphosphate (ATP), serotonin, and calcium.[94] Two thirds of platelet adenine nucleotides are stored in these granules, with an ADP/ATP ratio of 3 : 2, as opposed to 1 : 8 in the platelet cytoplasm. Platelet alpha granules contribute both prothrombotic and antithrombotic proteins as well as proangiogenic and antiangiogeneic proteins.[95] After platelet activation, the alpha granules centralize in the platelet and release their contents via membrane fusion with the open canalicular system.[95] Not all proteins present in alpha granules have the same origin. Some, such as VWF, thrombospondin, and platelet factor 4 (PF4), are synthesized in and packaged by megakaryocytes,[96] whereas others, such as albumin, immunoglobulins, and fibrinogen, are endocytosed from plasma.[97]

Dense Granule Defects

Patients with defects in platelet dense granules have a form of storage pool deficiency (δ-SPD).[98] Patients with δ-SPD exhibit a mild to moderate bleeding diathesis, as well as abnormalities in platelet aggregation. The second wave of aggregation is absent in response to ADP and epinephrine and virtually absent in response to collagen. Bleeding times in these patients are often prolonged. In 1969 it was shown that these patients have a deficiency in total platelet ADP, and this deficit was subsequently localized to the ADP pool of the dense granule. The abnormalities in the ultrastructure of the dense granules are heterogeneous, but most patients show a characteristic lack of dense granules by electron microscopy (see Fig. 30-5). One study has suggested a deficiency of multidrug-resistant protein 4 may be important in two patients with δ-SPD, although the molecular basis of this defect has yet to be resolved.[99]

The two most common SPDs are *Hermansky-Pudlak syndrome* (HPS: MIM 203300)[98] and *Chédiak-Higashi syndrome* (CHS: MIM 214500).[100,101] HPS is characterized by severe tyrosinase-positive, oculocutaneous albinism in association with photophobia, rotatory nystagmus, loss of visual acuity, excessive accumulation of ceroid-like material in reticuloendothelial cells, and a mild to moderate hemorrhagic diathesis. This disease is inherited as an autosomal recessive disorder, and although it occurs in many populations, it is seen with high frequency in people from the northwest part of Puerto Rico.[102] Patients exhibit bruising and epistaxis in early childhood. Fatal bleeding is rare, but a significant proportion of patients will have received packed red cell or platelet transfusions in their lifetime. The major cause of death in some genotypes is progressive pulmonary fibrosis, which generally begins in the late 20s or early 30s and may be related to higher plasma serotonin levels but also clearly involves defects in the pulmonary alveolar epithelium.[103] This disease is also associated with a 15% incidence of granulomatous colitis. To date, mutations in nine different genes (*HPS-1* to *HPS-9*) have been described in patients with phenotypic HPS, all of which encode for proteins, which are involved in the biogenesis of lysosome-related organelles such as melanosomes in melanocytes and delta granules in platelets. All known HPS proteins are components of one of four protein complexes: biogenesis of lysosome-related organelles complex 1 (BLOC-1), BLOC-2, BLOC-3, or adaptor protein complex 3 (AP-3). Some genotype-phenotype associations have also been documented.[104] For example, pulmonary fibrosis develops in patients with mutations in *HPS-1* and *HPS-4*, whereas this life-threatening complication does not develop in patients with *HPS-3*, *HSP-5*, and *HSP-6* mutations. In addition, patients with *HPS-2* mutations have associated neutropenia and a predilection for infections, particularly in childhood.[105]

CHS (MIM 214500) is a rare autosomal disorder that has been described in approximately 200 affected individuals.[105] It is characterized by immune dysfunction, platelet storage pool defects, and partial albinism. Patients often have a white forelock or ashen hair secondary to abnormally large melanosomes. Hematologic manifestations of this disease are characterized by the presence of large intracytoplasmic granules in leukocytes, lymphocytes, monocytes, and platelets (see Fig. 30-4, *D*), with a concurrent defect in mobilization of the marrow leukocyte pool, defective chemotaxis, and decreased bactericidal activity. Many other tissues also contain abnormal granules.[106] CHS patients often die in the first 2 decades of life of either overwhelming infections or an unusual lymphoproliferative disorder called the *accelerated phase*, which involves fever, anemia, neutropenia, and, occasionally, thrombocytopenia, hepatosplenomegaly, lymphadenopathy, and jaundice. The latter disorder occurs in 85% of patients.[105] Patients who survive to adulthood have progressive neurologic dysfunction.[105] These patients are particularly susceptible to Epstein-Barr virus infections.[107] The gene involved in CHS *(LYST)* is located on chromosome 1q42.1-42.2 and encodes a 3801–amino acid protein called LYST (lysosomal trafficking regulator).[108] This complex protein is a member of the BEACH protein family and contains several ARM/HEAT domains and a BEACH motif.[109] Mutations have been defined in an increasing number of affected patients and involve truncated products, although there is no correlation between residual protein length and clinical phenotype.[110]

Finally, *Griscelli syndrome* (MIM 214450) is a rare disease in which patients have partial albinism, silver hair, and neurologic defects and/or lymphohistocytosis with associated delta-granule deficiency. Major bleeding is rare in this syndrome. Patients have mutations in myosin Va, Rab27a, or melanophilin. One patient with a mutation in *RAB27A* and *AP3B1* showed a bleeding phenotype caused by impaired secretion, dependent platelet aggregation, and abnormal delta granules.[105]

Whole-mount electron microscopy is often used for the diagnosis of these disorders but is complicated by the fact that dense granule numbers may be low in normal platelets.[111] Some laboratories use serotonin release assays and assays examining ATP : ADP ratios to aid in the diagnosis of these disorders.[112] Some studies suggest that flow cytometry on mepacrine-loaded platelets may aid in the diagnosis because mepacrine is selectively taken up by dense granules.[113]

Alpha-Granule Defects

Patients with alpha-granule deficiencies have a bleeding phenotype similar to that of patients with dense-granule deficiencies, with mild to moderate bleeding, mild thrombocytopenia, and a prolonged bleeding time. Because of the initial light microscopic observation of gray platelets in the peripheral blood smear of these patients after Romanovsky staining, this disorder was termed *gray platelet syndrome* (GPS: MIM 139090).[114] On electron microscopy, the gray platelets are most notable for the absence or marked reduction of alpha granules (see Fig. 30-5, *D*). These platelets are also deficient in alpha granule–specific proteins such as PF4, VWF, factor V, and fibronectin.[115] Gray platelet aggregation to various agonists, especially thrombin, is impaired. These platelets have a delayed and blunted Ca^{2+}-mobilization response. The vacuolar structures seen in gray platelets appear to be aborted alpha granules that contain both P-selectin and $\alpha_{IIb}\beta_3$ in their membranes. They also contain a significant amount of proteins, including immunoglobulin and albumin, which are normally endocytosed into alpha granules. Endogenously synthesized alpha granule–specific proteins such as PF4 leak out. This latter phenomenon may contribute to the observed myelofibrosis and pulmonary fibrosis associated with this disease[116] and may also contribute to thrombocytopenia by negative feedback on megakaryopoiesis.[117,118] In 2011, several groups using various approaches simultaneously reported that mutations in *NBEAL2* are responsible for GPS; the approaches included linkage analysis followed by DNA sequencing, [119] whole-exome sequencing,[120] and RNA-sequencing[121] technologies. NBEAL2 belongs to a family of proteins containing BEACH domains; the proteins are highly conserved and important for protein-protein interactions, membrane dynamics, and vesicle trafficking. These diagnostic studies demonstrate the power of these technologies to identify molecular causes of inherited disorders of platelets in rare diseases and offer the possibility that in the future, underlying defects in such affected individuals will be resolved; this would not only enhance the understanding of platelet biology but would provide knowledge about an underlying platelet defect for many individuals.

In *arthrogryposis, renal dysfunction, cholestasis syndrome* (ARC: MIM 208085, 608552, 613401), patients also have absent alpha granules as a result of a defect in granule biosynthesis due to mutations in *VPS33B* or *VPS16B* (VIPAR), a VPS33B binding protein on chromosome 14 (C14orf133).[122] VPS33B is a vesicle trafficking protein, a member of the Sec1/Munc18 family of proteins, and is predicted to function in vesicle docking and fusion during alpha-granule development. Patients present with neonatal cholestatic jaundice, renal tubular acidosis, and arthrogryposis with severe failure to thrive.[123]

Other Granular Defects

A small number of patients have been described with *combined alpha-granule and dense-granule deficiency*.[124] In these patients, the dense-granule deficiency is often much more severe than the alpha-granule deficiency. Patients also have mild to moderate bleeding histories, and laboratory results are similar to those of dense-granule–deficient patients, with a decreased platelet ADP\:/ATP ratio in the cells and low levels of serotonin. In one patient with a severe deficiency in both alpha granules and dense granules, there was a deficiency in total platelet P-selectin; this finding suggests that in this disorder, unlike in GPS, in which there may be an alpha-granule–targeting defect, platelet granule formation itself may be defective.[125]

Quebec platelet syndrome is a rare disorder that results from the degradation of alpha-granule contents within the platelet because of ectopic urokinase-type plasminogen activator expression in developing megakaryocytes and its storage in alpha granules.[126] This disorder, inherited in an autosomal dominant pattern within two large kindreds in Quebec, was previously known as *factor V Quebec syndrome* because the initial observations in these patients revealed a relative intraplatelet deficiency of factor V.[127] These patients manifest moderate to severe delayed bleeding after surgery or trauma.[128] Bleeding can be controlled by antifibrinolytic therapy with tranexamic acid, but platelet transfusions are generally ineffective. The molecular abnormality responsible for this disorder was recently found to be a direct tandem duplication of a 78-kb genomic fragment that includes *PLAU* (the gene encoding urokinase-type plasminogen activator) present in Quebec platelet syndrome patients.[129]

QUANTITATIVE DISORDERS

Megakaryocytes are large, polyploid, terminally differentiated hematopoietic cells that release platelets into the bloodstream.[130] These cells arise from self-regenerating pluripotent stem cells that also give rise to all other hematopoietic lineages. Megakaryocyte lineage commitment involves a number of precursor stages, including CFU-GEMM (colony-forming unit–granulocyte, erythrocyte, monocyte, megakaryocyte), which in culture results in a mix of granulocytes, erythrocytes, monocytes, and megakaryocytes; CFU-EMM, which gives rise to mixed colonies of erythrocytes, monocytes, and megakaryocytes; BFU-Meg (burst-forming unit–megakaryocyte), which gives rise to a burst of 10 to 20 megakaryocytes; and CFU-Meg, which gives rise to a smaller megakaryocyte colony.[131] Megakaryocyte-erythroid progenitor (M cells are proliferating cells that express CD34 and CD38low that terminally commit to the erythroid or megakaryocytic lineage.[132]

Various growth factors regulate megakaryocyte differentiation at different points of megakaryocyte development. Certain cytokines stimulate proliferation of megakaryocytic progenitors, such as interleukin-3 (IL-3), IL-6, IL-11, IL-12, granulocyte-macrophage colony-stimulating factor, and erythropoietin.[130] Additionally, PF4 may be an important negative paracrine in megakaryocytes that is especially important in regulating platelet production after injury to megakaryocytes.[118] However, all the aforementioned growth factors and cytokines have very broad effects on all hematopoietic cell lines. The discovery and cloning of thrombopoietin (TPO), the ligand for the myeloproliferative ligand receptor (Mpl), opened a new perspective in megakaryocyte differentiation study. TPO was found to be a specific factor controlling megakaryocytic cell proliferation and maturation and platelet reactivity.[133] This 353–amino acid protein is homologous at its N-terminal with erythropoietin. Either the full-length protein, a truncated N-terminal TPO, or even mimetic peptides can dimerize Mpl and stimulate megakaryocytopoiesis.[134] On immature progenitor cells, activation of Mpl stimulates proliferation, much like IL-11 or c-kit ligand. On megakaryocyte precursors and megakaryocytes it leads to increased megakaryocyte differentiation and platelet formation. Targeted disruption in murine models of either the *Mpl* or *TPO* gene results in a decrease in platelet count to approximately 20% of normal.[135,136] Thus this cytokine pathway appears to be permissive for megakaryocytopoiesis but is not absolutely required for this differentiation.

MEPs differentiate into megakaryoblasts, small lymphocyte-like cells that undergo nuclear endoduplication and cytoplasmic enlargement and accumulate a body of specific proteins to form the mature megakaryocyte with a cell volume of approximately 10^4 to 10^5 μm^3. Each of these huge cells eventually results in the formation of approximately 10^3 to 10^4 platelets. Direct visualization of thrombopoiesis in the calvarium of mice suggests that mature megakaryocytes release platelets, large cytoplasmic fragments, and whole megakaryocytes at the endothelial cell border.[137] The circulating larger fragments may subsequently release platelets within the pulmonary vascular bed.[138,139]

The mechanistic basis of thrombopoiesis is beginning to be understood, but it does not appear to involve the extensive membrane system termed the *demarcation membrane system* that may represent inverted membranes. Rather, extensive pseudopods form and re-form in a dynamic process that eventually leads to a beaded appearance that fragments to form particles with the size and ultrastructural appearance of platelets.[140] This process can be inhibited by agents that disrupt microtubules and promoted by actin filament–depolymerizing agents, thus suggesting involvement of the cytoskeleton.[141]

The normal range of platelet counts is approximately 150 to 400 × 10^3/μL. Even more constant than the circulating platelet count is the circulating thrombocrit, which is the platelet count multiplied by the mean platelet volume, so there is an inverse relationship between platelet count and platelet size.[142] Regulation of megakaryocytopoiesis by TPO is in large part regulated by the platelet mass. TPO produced by the liver is secreted at a relatively constant level. As platelet mass rises, the amount of bound TPO increases and less is available for stimulation of marrow megakaryocytes. The inverse situation would also be true: As platelet mass falls, there is more free TPO to stimulate marrow megakaryocyte development.

The molecular basis for the regulated expression of genes during megakaryocytopoiesis is only beginning to be understood. This understanding has grown with the development of targeted disruption of hematopoietic genes in mice, which has demonstrated the importance of the transcription factors GATA1, NF-E2, and FOG-1 in megakaryocyte development.[143] Both GATA1 and FOG-1 knockdowns and NF-E2 knockouts result in viable mice with large and dysmorphic megakaryocytes and very low platelet counts.[144,145]

Disorders of Platelet Production

Disorders involving platelet production include congenital amegakaryocytic thrombocytopenia (CAMT), characterized by a complete absence of megakaryocytes; thrombocytopenia with absent radii (TAR), in which there is a decrease in megakaryocytes in infancy; amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS), characterized by skeletal anomalies and thrombocytopenia that improves with time; essential thrombocythemia (ET), resulting in increased platelet production; and disorders of hematopoietic transcription factors, often associated with an excess of dysmorphic megakaryocytes and platelets.

Disorders of the Thrombopoietin-Mpl Axis

Congenital amegakaryocytic thrombocytopenia (CAMT) is a rare disorder associated with very low platelet counts, absence or near absence of megakaryocytes in bone marrow, and risk for the development of bone marrow failure. These children have no skeletal abnormalities, and the platelet count does not improve with age and often necessitates bone marrow transplantation because of the severe bleeding and because of the risk of development of bone marrow failure. CAMT results from mutations in the receptor for TPO (*MPL*).[146] These patients demonstrate the importance of TPO signaling in normal hematopoiesis in that patients who survive long enough exhibit pancytopenia, usually during the first decade of life.[147] In addition, no *TPO* mutations have been found in this disorder or in other disorders associated with thrombocytopenia, including TAR (see later discussion).

In contrast, excessively high platelet counts (>600 × $10^3/\mu L$) are seen in *essential thrombocythemia (ET),* an acquired myelodysplastic disorder seen primarily in adults and associated with an acquired *JAK2* mutation (V617F) in 50% to 65% of cases. Other mutations in the TPO-Mpl signaling axis have also been reported.[148] A rare congenital form of familial thrombocytosis occurs in children that can be associated with enhancing mutations in the TPO promoter[149] or activating mutations in Mpl.[150,151] Unlike the ET associated with the JAK2 V617F mutation, myelodysplastic conversion in the congenital form is rare,[152] so it is unclear whether therapeutic intervention (suppression of the platelet count with hydroxyurea or anagrelide) is necessary, although antithrombotic strategies are often still used in the management of these children.

Thrombocytopenia and Orthopedic Abnormalities

Thrombocytopenia with absent radii (TAR) is one of the more common inherited disorders of platelet number and was first described in 1951.[153] This disorder involves hypomegakaryocytic thrombocytopenia and bilateral absence of the radii. Patients are born with platelet counts in the approximate $10^4/\mu L$ range; the count improves slowly and generally reaches nearly normal levels after the first year of life. During infancy, environmental stress, such as viral illness, can precipitate episodes of severe thrombocytopenia. Several TAR patients have had an associated storage pool defect and bleeding out of proportion to their platelet count. In addition, these patients have other hematologic changes, including leukemoid reactions in the range of approximately 30,000/μL and anemia, partly as a result of blood loss. About 30% of patients have recurrent gastroenteritis and bleeding. The major skeletal manifestation is complete absence of the radii but with functional thumbs. Other orthopedic abnormalities are seen in about 50% of cases, and the more severe the upper limb deformity, the more likely the patient is to have a lower limb deformity. Approximately 30% of patients have cardiac anomalies, including tetralogy of Fallot and atrial septal defects or neural defects.[154]

Megakaryocytes are present in the bone marrow, although there may be some decrease in comparison to what one would see in thrombocytopenia secondary to increased peripheral destruction. Serum levels of TPO in patients with TAR are elevated despite normal Mpl levels on hematopoietic cells. Bone marrow cultures from these patients reveal reduced numbers of megakaryocytes, and CFU-Meg do not grow in response to TPO.[155] Together, these findings suggest a disconnection between the TPO receptor and downstream signaling events. Inherited or de novo deletion of chromosome 1q21.1 is found in the majority of affected individuals but is also seen in unaffected family members.[156] Recently, whole-exome sequencing identified a second mutation as an SNP in the first intron or the 5′ UTR for the *RBM8A* gene.[157] Subsequent analysis of other TAR syndrome patients demonstrated that reduced expression of Y14 (the protein encoded by *RBM8A*), involving a combination of deletional and hypomorphic versions of *RBM8A*, is responsible for TAR syndrome.[157] Western blots showed a significant reduction in Y14, which is one of the four components of exon junction complexes. Exon junction complexes are involved in basic cellular functions such as nuclear export and subcellular localization of specific transcripts, translational enhancement, and nonsense-mediated RNA decay.[158]

Amegakaryocytic thrombocytopenia with radioulnar synostosis (ATRUS) is autosomal dominant and characterized by amegakaryocytic thrombocytopenia, skeletal anomalies (including radioulnar synostosis, hip dysplasia, and clinodactyly or syndactyly), and sensorineural hearing loss.[159] The thrombocytopenia in these patients occurs in the neonatal period and may be severe, but often resolves in the first few years of life.[160] Mutations of *HOXA11* have been demonstrated as the molecular abnormality in most patients with ATRUS.[161] HOXA11 is a member of the homeobox group of regulatory proteins that play a role in hematopoietic proliferation and differentiation. Studies in animal models have shown the role of HOXA11 in forearm skeletal development. However, although bone marrow from HOXA11-overexpressing mice shows increased immature megakaryocyte colonies,[162] a clear role in megakaryocytopoiesis has not been defined.

Platelet Disorders Secondary to Transcription Factor Defects or Unknown Biology

X-linked anemia with severe thrombocytopenia (MIM 300367) secondary to mutations in *GATA1* has been reported.[163] There have been mutations described in different kindreds resulting in at least two distinct phenotypes with thrombocytopenia: *XLT (X-linked thrombocytopenia)* and *XLTT (X-linked thrombocytopenia with thalassemia)*. The major differentiation between the two types is the presence of dyserythropoiesis (in XLT) versus a thalassemia-like hemolytic anemia with splenomegaly and abnormal beta chain production (XLTT). The differences in phenotype may be related to whether the mutated GATA1 retains its ability to bind to FOG-1 (R216Q: XLTT) or whether the GATA1 interaction with FOG-1 is disrupted (XLT: V205M, G208R, G208S, D218G). The megakaryocytes in the marrow of these patients are similar to those described in GATA1–knockdown mice; they are numerous and large, with poorly organized granular content and nuclei pushed off to the side (see Figs. 30-4, *C* and 30-5, *F*). Some of these patients have a macrothrombocytopenia and have been described as having a form of GPS.[164] Patients present with significant bleeding early in life (especially XLT patients), with varying degrees of anemia.[163]

Familial platelet disorder/acute myelogenous leukemia (FPD/AML: 601399) is a dominantly inherited thrombocytopenia with platelet counts around 100,000/μL that is often associated with a bleeding diathesis out of proportion to the decreased platelet count. Platelet studies in some families show a classic and profound storage pool defect, but the precise defect can vary between families. There is about a 50% lifetime risk of AML developing in any affected family member, as well as an increased risk for other cancers.[165] Studies have shown that in many of these extended families, the defect resides in the *RUNX1* (previously *CBFA2* or *AML1*) gene (chromosome 21q22.1-22.2), resulting in defective RUNX1.[166] RUNX1 is a nuclear transcription factor involved in early hematopoietic differentiation from endothelial cells and is important for myeloid differentiation. Translocations involving RUNX1 result in AML or related cancers. RUNX1 is also expressed and important during megakaryopoiesis. The majority of FPD/AML mutations described are within the DNA-binding Runt domain of RUNX1 and affect heterodimerization of RUNX1 with PEBP2β/CBFβ. Haploinsufficiency of RUNX1 has been shown to affect DNA binding, heterodimerization, nuclear localization, and transactivation functions. Recently, *RUNX1* mutations have also been shown to dysregulate myosin II in megakaryopoiesis.[167] Additionally, several patients have now been described with deletions involving the *RUNX1* gene with various phenotypes that depend to some degree on the size of the deletion.[168]

Jacobsen syndrome (MIM 147791) involves a deletion of the terminal portion of chromosome 11q (23-ter), a region that includes the *ETS1* and *FLI1* genes. Ets1 and Fli1 are related zinc finger nucleases critical for megakaryopoiesis. *FLI1* is within the minimal critical region required for manifestation of the disease, and its overexpression can drive MEP cells into megakaryocyte differentiation. Over 200 cases have been reported; most cases arise from de novo deletions, which are variable in size. Almost all patients present with neonatal macrothrombocytopenia with abnormally large alpha granules of *Paris-Trousseau platelets* (MIM 188025) and increased numbers of dysmorphic megakaryocytes in the bone marrow. Additional defects in the heart, kidney, brain, and other organs are often more problematic than the platelet disorder. The thrombocytopenia may be severe at birth but tends to improve with age, although a mild to moderate bleeding diathesis persists.[169]

ANKRD26-related thrombocytopenia (ANKRD26-RT) is a recently characterized autosomal dominant thrombocytopenia with normal platelet size, which was previously mapped to chromosome 10p11.1-p12. These patients have moderate thrombocytopenia and mild bleeding. The bone marrow shows dysmegakaryopoiesis with many small dystrophic megakaryocytes with hypolobated nuclei but without clear abnormalities in platelet morphology.[54] ANKRD26 is a protein of unknown biologic function. The mechanism by which *ANKRD26* mutations result in thrombocytopenia is not known. Patients may have an increased risk of leukemia.[170]

Thrombocytopenia Associated with Macrothrombocytes

Another inherited platelet disorder involving large platelets and thrombocytopenia besides the disorders related to the GPIb/IX receptor, GPS, platelet-type VWD, and transcriptional factors is the autosomal dominant disorder known as *myosin heavy–chain 9–related disorder* (MYH9-RD). The disorder was previously called May-Hegglin anomaly (MHA: MIM 155100), Sebastian syndrome (MIM 605249), Epstein syndrome, and Fechtner syndrome (MIM 153640). In this disorder macrothrombocytes are associated with thrombocytopenia and normal coagulation studies. Leukocytes contain large spindle-shaped inclusions known as *Döhle bodies* (see Fig. 30-5, *E*). Additionally, patients may have sensorineural deafness, nephritis, and ocular abnormalities (in particular, cataracts). The original disorders were separately classified, but it is now clear that all are due to mutations in the *MYH9* gene encoding the cytoskeletal protein nonmuscle myosin heavy-chain IIA (NMMHC-IIA). Bleeding symptoms in this disorder range from mild to moderate (bruising, epistaxis, and menorrhagia), and severe bleeding episodes are rare. Platelet counts range from severe thrombocytopenia, with platelet counts of approximately 30,000/μL, to mild thrombocytopenia, with platelet counts of around 100,000/μL; giant platelets are present on peripheral blood smears. Diagnosis can be confirmed by immunofluorescence staining of peripheral blood showing aggregates of abnormal nonmuscle myosin IIA (NMM-IIA) within leukocytes and platelets. Because the bleeding issues are often limited, further evaluation of affected patients should focus on screening for hearing loss, ophthalmologic impairment, and renal dysfunction in the patient and family members.[171,172]

NMM-IIA exists as a hexamer of two heavy chains and four light chains. NMMHC contains an N-terminal motor domain (head) and a C-terminal rod domain (tail). Although genotype-phenotype correlations are not perfect, mutations within the head appear to result in more severe disease with more significant thrombocytopenia and higher risk for hearing and renal impairment. However, within families containing the same mutation there is significant heterogeneity in phenotypes.[172]

Specific mutations in *ITGA2B* and *ITGB3* have also been described to cause an autosomal dominant form of macrothrombocytopenia.[173,174] While biallelic mutations in these genes result in GT (described earlier), mutations resulting in a partially constitutively active GPIIB-IIIa complex, through disruption of the interaction of cytoplasmic tails, alter megakaryocyte: fibrinogen interactions within the bone marrow and alter platelet production.[175] These patients have thrombocytopenia with different degrees of platelet macrocytosis and some altered platelet function.

There are multiple complex disorders associated with thrombocytopenia, including congenital sitosterolemia resulting from loss of function mutations in *ABCG5* or *ABCG8*, which play a role in enterocyte and hepatocyte exclusion of plant sterols. The clinical presentation of these patients is variable, but many present with stomatocytosis, thrombocytopenia, and large platelets associated with elevated plasma concentrations of phytosterols.[176]

Another complex disorder associated with macrothrombocytopenia results from mutations in the filamin A gene *(FLNA)* located on chromosome Xq28. The most commonly described disorder associated with mutations in *FLNA* is *periventricular nodular heterotopia*. Several patients have been described with PVNH and thrombocytopenia with abnormal platelet and megakaryocyte morphology. Recently, a novel missense mutation in *FLNA* was described in a woman presenting with isolated thrombocytopenia that had been initially diagnosed as immune thrombocytopenia.[177]

Thrombocytopenia Associated with Microthrombocytes

Wiskott-Aldrich sydrome (WAS: MIM 313900) patients have microthrombocytopenia, but the phenotype involves multiple aspects of platelet and lymphocyte biology. WAS was first recognized in two case reports as a sex-linked disorder with thrombocytopenia and eczema.[178] Platelets are small, usually half-normal volume, and the platelet mass is decreased.[179] There appears to be an associated platelet storage pool defect. The thrombocytopenia seen is severe and can be less than 10,000 platelets/μL. These patients may also have a severe immune defect with an impaired ability to form antibodies to carbohydrate antigens and appear to have a defect in B and especially T lymphocytes. As in the 22q deletion syndrome, WAS can lead to an immune-based thrombocytopenia and ultimately to a leukemic- or lymphomatous-based thrombocytopenia. Splenectomy, although it increases the risk for opportunistic infection, often alleviates the thrombocytopenia and bleeding in this disorder. Immune-related complications respond variably to steroids, intravenous immunoglobulin, vincristine, or plasmapheresis.[182] Bone marrow transplantation has been efficacious.

The gene involved in WAS (MIM 301000) and a milder version termed X-linked thrombocytopenia (MIM 313900), which is not associated with the severe immunologic defects, has been localized to the short arm of the X chromosome (Xp11.22). The encoded protein WASP is 501 amino acids long, has no transmembrane domain, but has two highly charged C-terminal domains.[180] In addition, there is a potential nuclear localization signal. There is a pleckstrin homology domain and a cofilin domain by which WASP can depolymerize actin. WASP expression is limited to lymphocytes and platelets. WASP binds to a number of intracellular signaling proteins such as the Rho family member guanosine triphosphatase (GTPase) Cdc42. Tyrosine phosphorylation signaling in the cell appears to cause WASP to become bound to cytoskeletal proteins such as PSTPIP (WIN) and to be involved in megakaryocytopoiesis.[181]

Additional proof that WASP was involved in WAS came from the original description of the gene. One affected patient had a single base deletion, a second had a G→T transversion that led to an Arg86Leu substitution, and a third had a G→A transition of the same Arg leading to a His substitution.[180] Since this patient was identified, the number of defined mutations has increased (almost 300 mutations have been described), and their relationship to the genetic severity has been better defined. Patients have been described with isolated X-linked microthrombocytopenia,[182] and these patients have missense mutations in the *WAS* gene, only some of which overlap with the mutations seen in WAS. To complicate matters, the *GATA1* gene is closely linked to the *WASP* gene, and this may limit the usefulness of linkage studies for defining which of these two genes is affected in a patient with X-linked thrombocytopenia.
